Foreword

VOLUME 52 of the TRANSACTIONS OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS contains 35 individual sections published during 1930 under the sponsorship of the Society's 15 professional divisions, as well as its annual Record and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections. Other papers published by the Society but not included in the Transactions may be located by means of the Record and Index which forms a part of this volume.

The papers published in this volume were issued originally in pamphlet form. These pamphlets appear in sections, each section being sponsored by one of the Society's professional divisions. A member of the Society may register in any three of the fifteen professional divisions and receives in pamphlet form as they are issued the sections of Transactions sponsored by those divisions.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on page 97 of the Record and Index. Copies of the bound Transactions have also been set aside for sale.

At the end of Volume 52 will be found the Record and Index of the A.S.M.E. for 1930. This is the permanent record of the Society's activities for the year, and includes lists of committees, reports of meetings and committee activities, and memorial notices of deceased members. The indexes include those of special publications, and of *Mechanical Engineering*. Printing of the Record and Index in this form was ordered by the Council of the Society, and returns to the Transactions material of permanent historical value which has been issued for the past three years (1927–1929) as a separate publication.

NUMBERING AND ARRANGEMENT OF PAPERS IN COMPLETE TRANSACTIONS

In this volume the papers of each section are grouped together and are numbered serially. The different sections follow each other alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. Each of the two books forming parts I and II of Volume 52 contains a complete index of subjects, authors, and discussers to both parts of the volume so that either may be consulted. The arrangement of the index and designations for locating material are explained at the beginning of the index.

CONCERNING BLANK PAGES

The papers in each section of the Transactions are printed separately so that they may be available as reprints. This makes it necessary to print each paper so that the number of pages is a multiple of four. Because of this, blank pages will be found at the ends of papers which do not completely fill the printer's form.

Progress in Industrial Management

Contributed by the Management Division

Executive Committee: W. L. Conrad, *Chairman*, Robt. E. Newcomb, *Vice-Chairman*, G. W. Kelsey, *Secretary*, C. E. Hagemann, Wm. B. Ferguson, and Chas. W. Lytle

WITH the nation-wide interest shown by business men in the problems of "waste in industry" has come a steadily increasing effort toward the elimination of this waste and the introduction of methods of managerial control in industry. As the manufacturers, distributors, and consumers have studied existing waste of time, material, and human energy in our productive and distributive processes, their sense of responsibility for the waste, its causes, and its correction has resulted in a determined effort for its elimination. Not only have these industrial interests asked and received cooperation from one another, but they have also appealed to the Department of Commerce, Chamber of Commerce of the United States, and professional societies for cooperation.

This cooperative effort has helped to reduce inventories and idle investment, to increase the turnover of inventories, to increase sales volume, to reduce manufacturing and selling costs, to increase profits and values, and to improve quality and service. The success of the simplification movement has stimulated interest in standardization of grade and quality of products; and has advanced materially the development of specifications, particularly the more general use of specifications in buying.

The elimination of waste in industry is taking a new turn. It is now realized that, besides the waste of concrete materials resulting from overdiversification and other causes, there is a tremendous waste through the use of inefficient processes for the production, transmission, and utilization of energy.

The history of the recommendations made by the many agencies that have studied the problem of managerial control, shows many good examples of that flexibility which enables the simplified-practice recommendation of any industry to keep pace with changing consumer demand. Adding items as new developments require and discarding the obsolete have a stabilizing influence to retard any rapid increase of unnecessary diversification such as frequently takes place in an industry that has no definite program of simplification. Manufacturers have justly benefited through fewer interruptions for adjusting machinery, the release of unproductive space for other purposes, etc.

The interest that has been manifest in managerial control in industry during the past few years, and especially the searching investigation that the financial institutions now make into an industry before they agree to any proposed expansion of that industry, or to the expenditure of any considerable amount of capital, shows conclusively that more attention is being given to managerial control than was formerly the case. Continuation of this practice augurs well for the future of all industries.

Another tendency which is becoming manifest is the realization that conservation and efficient utilization of resources apply to man-made as well as to natural resources. So much capital is now tied up in our great industries, and so many people are dependent upon them, that it is no longer possible to scrap an entire industry because science has developed a new product to replace the one which that industry turns out. The complete abandonment of certain facilities in favor of others without careful study will not occur so often in the future as it has in the past. The almost complete overthrow of our highway and waterway systems by the railroads, in the end proved an economic blunder. We know now that research could have coordinated them with tremendous savings. The railroads have learned a lesson, and the result is the present effort to coordinate rail, highway, and aerial transportation facilities, with the hope of producing a unified and efficient system.

Managerial Control in Industry

With the demand for economy increasing until it has become a most important factor in the onrush of industry, little is wasted nowadays. Profitable business enterprises are built upon by-products and materials that once were thrown into the discard. No longer are sawdust, waste oils, scrap iron, and miscellaneous factory débris cast aside to be forgotten.

The report of the Committee on Recent Economic Changes says in reference to managerial control in industry:

> The chapter of this report on industrial management prepared for the committee, presents the results of analysis of 100 fair samples of normally successful established business institutions, so chosen as to show prevailing practices. This chapter shows that more men are being brought within managerial responsibilities and that the "big boss" is passing. There is today not only more production per man, more wages per man, and more horsepower per man, but more management per man as well.

The increasing introduction of scientific management methods in America, the intensive competition, and the increasing importance of the control of details for desired profit is making the importance of detailed managerial control through thermometrical budget and cost information more and more important. Budgets and the actual performance in conformity show the greatest progress.

The improved and wider usage of budget systems is a definite step of management progress, and is bringing about greater detailed and intelligent coordination between production and distribution.

The effort toward waste elimination in America is probably doing more to advance managerial control and increase profits than any other single element, since it compels detailed study of operation.

Better Management

"There are greater profits through better management, as revealed through simplification, the elimination of waste, more highly efficient personnel, and a finer spirit of cooperation," said Craig B. Hazelwood, vice-president of the Union Trust Company of Chicago, in a recent article. In this article Mr. Hazelwood stated that "the amazing spectacle of the youngest of nations in the vanguard of commercial progress pays silent tribute to the creative genius which has so distinguished American business." Continuing, he said;

> In the face of this remarkable development it is natural, but unfortunate, that the emphasis be placed upon size and volume, attributes which can never measure up as the ultimate aim of industry. In the fast-running current of these days, we need to take a new grip upon the practical realities of business, realizing that though we set up the greatest retail business, the largest factor, the biggest jobbing organization in the country and have not profits we have failed to be of permanent service to the public. Fortunately, we are now in the

morning hours of a new era in scientific management, revealed through simplification, the elimination of waste, more highly efficient personnel, and a finer spirit of cooperation.

Ethical Standards

The most outstanding contribution of the year in the field of industrial literature is the two-volume report entitled "Recent Economic Changes," issued by the National Bureau of Economic Research. This is an outcome of the President's Conference on Unemployment and is a most searching study. Every conceivable phase of industry is covered and the very best information is made available regarding all of the important trends. Much stress is placed on the social efforts of our greater productivity. Greater earnings and shorter hours together have increased the demand for goods, and this demand is by no means restricted to necessities. To quote briefly: "The survey has proved conclusively what has long been held theoretically to be true, that wants are almost insatiable—that one want satisfied makes way for another. The conclusion is that economically we have a boundless field before us, that there are new wants which will make way endlessly for newer wants as fast as they are satisfied."

The connection between scientific research and industrial management is more direct than might at first be imagined. The development of new and improved materials and of better and more economical processes has a profound influence on management methods.

The past year has shown an increasing realization of the fact that management can be truly efficient only if the thing managed is efficient in itself. The efficient management of a horse-drawn dray will not result in lowering the cost of transportation to that by motor truck. Industrial managers are looking more and more deeply into the equipment and processes employed in their plants to make sure that they are the best for each particular purpose. Often the manager is able to see chances for improvement which might be overlooked by those more directly concerned with the actual mechanics of the business.

Wage Incentives

For some time a tendency has been developing to make more and more group applications of incentive plans. This is a natural accompanyment of mass production in that more and more work is interdependent. As in all new things, there is, however, a danger of this change swinging too far. Since task standards need only be set for the whole assembly and the subordinate parts merely balanced, it is an easy way to avoid some of the preliminary job standardization and much of the paper work in operating. If equal results were possible there could be no objection, but it is well established that group effort is neither that of the least efficient or that of the most efficient, but a mean between. In fact, the effort may be even below the mean if leadership is not properly exerted, and leadership cannot be properly exerted when groups are large. It is in this respect that group applications have been carried beyond their suitability. Such companies as the Western Electric have gone through this stage and are now deliberately returning to individual applications, except where jobs are definitely interrelated and where leadership can be effective. Plans which use the man-minute for production control have spread rapidly during the year and are undoubtedly achieving a greater unity of control than anything ever achieved with the man-hour, although the reason for this is not fundamental. It simply happens that such plans as those of Bedaux, Haynes, Parkhurst, and Dyer have worked out comprehensive systems for unified control and are not installed without control. Office work and all indirect work in the factory are just beginning to have extra-financial incentives. This is merely because such incentives have to follow job standardization, and employers are now learning to apply such standardization to the more difficult types of tasks.

At the same time, incentives are being extended to supervisors and executives, some on a profit-sharing basis, but many on a real accomplishment basis. The former is effective for the highest executives, but much less so for those below the general manager, because the relation between the reward and the effort is always remote under the profit-sharing type of plan and may even be quite unrelated. Furthermore, incentive plans are being scrutinized on their real merits and are not being accepted so readily because of high-pressure sales on the part of consultants. (C. W. Lytle, "Wage Incentive Methods.") It is not unusual in well-managed companies to have as many as 80 or even 90 per cent of the employees on an incentive basis today. Some companies are even applying incentives to the elimination of accidents. It has come to be the accepted thought that safety is primarily a management responsibility, but the fact that our industrial accidents last year amounted to $1,000,000,000 indicates the need for still better attention to this problem.

Obsolete Equipment and Its Relation to Profits

Probably the most important questions that confront the manufacturer today are the relation between the condition of productive equipment and profits, and the replacement of machinery which in point of service may have many years of usefulness, but which is incapable of satisfying the latest fancies of the consumer market or competing with more recent and improved machinery. This has been a difficult point for manufacturers, and has prompted a request for a study of this problem.

The important phases of the industrial-equipment studies are, (1) to bring out facts showing the relation of equipment obsolescence to production costs, and (2) to discover, if possible, a means for correctly evaluating and providing for obsolescence in cost accounting. The first result is expected to be obtained by the study of machinery among manufacturers of the several classes of machinery. The second result is expected from an investigation among the users of such machinery.

The practical value of such studies will be, it is hoped, the establishment of a truer accounting for obsolescence as a hazard rather than an arbitrary compromise as at present. Wear and tear, or depreciation, is a scientific problem, and can be determined with considerable accuracy. Obsolescence is more nearly analogous to fire. As a risk it cannot be predetermined any more than can the date a building will burn. An arbitrary basis of accounting for the two factors does justice to neither, and fails adequately to provide for a fund for replacing the machinery when its value has been destroyed by the factor of obsolescence.

Keen competition, as well as reasons other than inefficient machinery, has caused some of our plants to liquidate.

Plants that have had the money to invest have discarded old equipment as far as possible, but those industries which have been running and which have antiquated machinery have been dragging along at a loss or no profit, or have liquidated.

The chapter on Industry. in the report of the Committee on Recent Economic Changes, gives striking evidence of the differences in utilization of productive factors by the prosperous as compared with more backward manufacturing industries. The yardstick adopted is productivity per man-hour. In general, where productivity has increased, industry has been prosperous; where it has increased but slightly or has decreased, the industry is in difficulty.

Utilization of power, of buildings, and of equipment are important factors. The increase in the manufacturing of machinery, for example, probably approximates or perhaps reaches higher levels than the increase in industrial power.

Experience is showing that in these competitive days the mathematical relation between obsolete machinery and profits is an inverse ratio.

A few months ago, Ray M. Hudson, Assistant Director, Commerical Standards, said that:

> As competition increases, price cutting occurs, until the craze for volume swells sales expenses, increases distribution costs, and reduces profits, even though the factory be operating at capacity. In cases where factory capacity is in excess of current sales volume, pressure for greater volume becomes acute, and greater effort is made to secure it. New ideas in selling develop.
>
> Among recent proposals is "progressive obsolescence," meaning the quickening of sales by inducing people who can afford to buy a greater variety of goods on the same principle such people now buy autos, radios, and clothes, i.e., "not to wear out but to trade in or discard after a short time, when new and more attractive goods or models come out." While some stimulation of obsolescence is not uneconomic, the danger lies in its probably application to buyers who cannot afford it, and who might better put more of their income into more permanent investments. That uncontrolled obsolescence has great potentialities for economic waste and loss is obvious. Too high a frequency of purchase is relatively as wasteful for the consumer as too high a frequency in change of design, size, style, or model is for the manufacturer and the merchant.

Standardization as a Factor of Management

Mass production is dependent upon the adoption of dimensional standards. Standards of this kind—in fact, most of the standards in existence today, as distinguished from "quality specifications"—have been developed by producer organizations operating either as individual firms or as groups of firms brought together through some such agency as a trade association.

With few exceptions, industrial executives are in favor of such dimensional standards as will permit mass production, and of quality specifications for the materials purchased by them. The more progressive of the executives are in favor of service or performance specifications for goods sold by them and their competitors, although not a few of them are opposed to "composition specifications," which are looked upon by them as tending to retard improvements.

To the extent that standardization does in fact retard improvement it is disadvantageous; to the extent that it eliminates the less desirable in favor of the better commodity it is advantageous. At an ever-increasing rate industrial executives are realizing that when properly carried out standardization simultaneously eliminates the unworthy and identifies and sets forth the best, not as a finality, but as a starting point for improvement.

Reasonable specifications, formulated after thorough interchange of ideas and experiences of the manufacturer and the user, and setting forth those requirements considered essential to safeguard the consumer without hardship to the manufacturer, serve to show to both parties to the contract what service the commodity must render, and how it must be manufactured in order to fit it for use. It is to the best interest of all persons concerned that the specifications be formulated jointly by both parties to the contract, working together harmoniously, each benefiting from the knowledge and experience of the other.

Management may be defined as the judicious use of means to accomplish an end. Business management naturally consists of the careful guidance of men and material in the production and sale of a commodity that will produce the desired end—namely, dividends.

The industrial community is receiving valuable assistance in establishing means for accomplishing these results from the Bureau of Standards.

Management is vitally affected by nationally recognized grades, by standards of quality. To fully analyze this question it is always well to consider it from the standpoint of the interests of the various branches of industry.

One of the commercial standard publications quotes R. P. Lamont, Secretary of Commerce, as saying that:

> Standards constitute the common language, even the common law, of modern industry and commerce. Certain standards, such as those used for weights and measures, are essential for public convenience, health, of safety, and have been fixed by legislative enactment. Mandatory standards of this character, however, are few in number when compared with the large and steadily growing volume of standards developed by industry and commerce and voluntarily maintained.
>
> Recognized standards of this character developed by cooperative effort on the part of designers, manufacturers, distributors, and users constitute a powerful force for eliminating waste in production and distribution. Simplified practice, meaning elimination of unnecessary variety of products, and concentration on a small number of standard products, offers many striking examples of the enormous benefits to be gained through voluntary cooperation. Many different groups must cooperate not only in developing standards but in establishing and maintaining them in general use.
>
> Such voluntary cooperation is of equal value in providing means whereby standards may be modified to meet changed conditions or new development.

Continued calls for cooperation in the endeavor to establish standardization as a factor in management have caused agencies of the Government to augment its service to industry, and its Division of Trade Standards is working with nearly fifty different commodity groups in perfecting standards of grade and quality for their products.

The enlarged export business of the United States and the rapidly growing use abroad of simplification and standardization has brought a demand for further cooperation in the translation of American standards and specifications into foreign languages for the convenience of foreign consumers. Service of supply, including transportation facilities and means of communication, has advanced to the point where buyers no longer shop exclusively in the nearest market.

Russell Forbes, the nationally known expert in purchase practice, in his book entitled "Government Purchasing," says, according to the A. S. A. Bulletin, that: "The treatment of the purchasing problem will be of direct interest not only to federal, state, county, and municipal buyers, but also to every one concerned with the allotment and expenditure of tax moneys, and to purchasing agents of large industrial concerns." He recognizes with unusual clarity the importance of standards as a factor in the purchase problem, and cites important instances of savings gained through the standardization technique.

One factor which has contributed largely to the notable increase in manufacturing efficiency in the last two decades has been the development of standards in cost accounting. The old system of trial and error has been replaced by accurate facts, and many wasteful production practices have been thus discovered and eliminated. The key to the practical use of cost accounting in manufacturing has been the study of the cost of producing individual items and of performing individual operations.

Standardization has unquestionably been a definite factor in inventory and cost reduction. Its application, however, in a wide manner seems to be more confined to staple articles not involving style or temperamental selection. Its future application might possibly, with beneficial results, be directed to standardization of an article of one concern, rather than of the same article as produced by many.

The great competition today is between industries, and it is natural, therefore, if members of a given industry desire to maintain the standing of the industry as a whole and a recognized standard for their product, they should set up a minimum level for their commodity below which quality shall not be allowed to fall, in order that the public may buy with assurance and confidence, and that the commodity as a whole shall retain the goodwill and command the respect of the purchaser.

Coordination of Production and Distribution Methods

The answer to coordination in production and distribution methods is not price cutting, but reduction of waste in physical distribution, says *Distribution Economy*. In this connection, the magazine asks, "When your goods leave the production line, are they handled with the same mechanical skill that produced them?"

Efficiency and scientific management are essential factors in the successful operation of the modern industrial plant. Great progress has been made in these directions by American manufacturers during the last decade. Waste has been eliminated in a thousand different ways through improved business practice, and through simplification of processes and methods of manufacture.

Dunn's International Review, in discussing this subject editorially, says:

> With this lowering of production costs, it is now recognized that the next great field for the reduction of industrial waste is in methods of distribution. Today, the necessity for satisfactory and economical distribution as a means of passing production economies on to consumers is reinforced by the realization that, in many instances, effective distribution is the deciding factor in the new group competition between industries, commodities, and distributors. The idea of a smoother and more economical passage of merchandise from producers to consumers is growing rapidly, and it is to be hoped that the problem will permit of an early solution.

Relatively little progress has yet been made in analyzing distribution costs from the standpoint of the cost of handling individual items or performing individual services. There has been some progress made, and several agencies are attempting some work in this field. Investigations in wholesale and retail distribution for several lines of trade, with particular reference to the small as well as the larger producer and also to the several methods of distribution, show the possibilities for reducing costs through more uniform methods. The purpose of these reports is not so much to provide comparative data on operation costs or to specify wasteful practices, but rather to present a method for functional-costs allocation which may easily be adopted by any industry or branch of industry in determining the profitableness of their own individual commodities, customers, or service.

There have been several attempts in some particular lines of industry at consolidation of plants producing similar goods to bring about the coordination of production and distribution methods. Some of these mergers have been accomplished and should result in diminishing the competition in the distribution of the product.

Various chapters of the report of the Committee on Recent Economic Changes stress the striking progress in coordination of production and distribution. Progress in the later years of the decade has been particularly striking. A recent report, signed by sixteen of the most important figures in industry in the country, including President Hoover, makes this striking statement:

"In the marked balance of consumption and production, for example, the control of the economic organism is increasingly evident," and the Committee insists that "it would seem that we could go on with increased activity, but only if we develop a technique of balance."

Waste Elimination and Its Effect on Industry From a Managerial Standpoint

During the past year considerable progress has been made in reducing factory waste. Early in the year a committee was organized to encourage as an annual national program the holding of campaigns within industry to eliminate waste. During April a large number of companies held an exhibit of waste campaigns which consisted of exhibit boards of factory waste gotten by employees, as well as meetings to stimulate interest in the boards and in contributing suggestions as to how waste might be reduced. Prizes were given for the best board and for every worth-while suggestion.

The history of this movement dates back to the yearly Management Week, which, after being held several years, was discontinued last year as it was felt that the work of attracting attention to better management methods and the responsibility of management could more effectively be carried by individual organizations. On the disbanding of the Management Week Organization, attention was called to the fact that in 1926 the topic of Waste Prevention had been sponsored by the Week and that as a part of it an exhibit campaign had been arranged by Westinghouse Electric and Manufacturing Company at East Pittsburgh. This campaign has had such successful results that the Newport News Shipbuilding and Drydock Company, and later the subsidiaries of the U. S. Steel Corporation and many other plants, organized campaigns. The amazing savings and other benefits secured from the campaigns brought the demand for coordination and stimulation of the work, as a result of which the committee mentioned above was organized.

As part of the movement in 1929, besides the number of companies that put on campaigns there were elimination-of-waste meetings held in over twenty-five cities. Hundreds of booklets describing campaigns already held and how to organize them were distributed during the year to company executives, and it is planned to continue the work annually every April. The most spectacular and successful campaign was organized by the Oakland Motor Company at Pontiac, Mich. Their campaign, called a "War on Waste," opened with a sham battle by the state guards against a waste stronghold, and was followed by an extensive two-weeks' campaign. Eleven hundred employees contributed over twenty-five hundred suggestions on reduction of waste, of which a third were classed as valuable, and it was estimated by the company that half a million dollars would be the immediate saving of the campaign, with a like amount to be secured later.

The tendency to more serious thinking on the subject of waste elimination is developing a better basis for real action along this line in industry. Salvaging is only a minor part of real waste elimination. We need to give more thought to *"not wasting,"* as Mr. Ford says, than to reclaiming what is waste.

In the attainment of the elimination of waste, whether of time, material, or human energy, this fact is basic and fundamental. It affords a common cause in which all interests or elements find many opportunities for growth and for the creation of greater wealth, not alone for the few but for the many—in fact, for the Nation.

Waste elimination, by the reclamation and reuse of materials, and the development of commercially valuable by-products, has also been very striking. In the case of reclaimed rubber alone, the figures run to more than twenty millions in a single year.

Waste-elimination programs offer every one in industry an opportunity to cooperate, and are now recognized the world over as a fundamental factor of force operating to help stabilize business, to lower costs of production and distribution, and thus lower the cost of living. Beyond that it works to advance still further our standard of living to conserve our material and human resources.

Greater possibilities for coordination with other activities also obtain. In this connection, attention is again called to the tremendous wastes in distribution, estimated at eight billion dollars annually. At least three billion of this is attributable to waste in physical handling and transportation. A major portion of the other waste also occurs through lack of simplication of method and practice.

W. L. Conrad, *Chairman.*

MAN-52-2a

Twelve Years' Experience With Economic Production Quantities

By C. H. BEST,[1] INDIANAPOLIS, IND.

For twelve years economic production quantities have governed the sizes of production orders in the plant of Eli Lilly and Company, manufacturers of pharmaceutical and biological products, at Indianapolis, Ind. This paper outlines briefly some of the major results of this practice, both direct and indirect, and discusses some of the cost-accounting problems that were encountered in the derivation of the formulas. The discussion of cost-accounting problems is limited to such problems as might be generally encountered in other plants.

THE firm of Eli Lilly and Company manufactures and ships from stock approximately 2400 products which are marketed in over 8500 different packages. The problem is to maintain stocks of these 8500 different items at the lowest possible combined cost of labor of preparation and charges for carrying the merchandise until it is sold.

It was recognized long before 1917 that the quantity produced in a single batch was one of the important factors in determining the cost of producing and carrying the merchandise. Charts and curves were drawn to assist the individual whose judgment determined the batch sizes. These aids were better than nothing, but they could not even approach the solution of the problem.

In the early part of 1917 work was begun on the assembly of data from which to derive mathematical formulas that would determine the economic production quantity. The task was to express algebraically the total cost of producing a batch of merchandise and of carrying that merchandise until it was sold. This expression has been termed the "total-cost expression," and will be referred to by this term. The first derivative of the total-cost expression, when set equal to zero and solved, gives the economic production quantity or the cheapest batch size that can be made. Larger and smaller batches than the economic production quantity will both produce a higher unit cost than batches made in this exact amount.

The simplicity of the calculation for determining economic production quantities is shown by the following example: The formula used is

$$N = 262.8 \sqrt{\frac{Y}{M + 202}}$$

where N = economic production quantity in units
Y = number of units sold per year, and
M = cost of material in cents per unit.

Let Y = 14,000 gallons and M = 850 cents per gallon; then the solution of the formula gives N = 958 gallons, or the economic batch size.

The solution is an easy slide-rule calculation.

To make a larger or smaller batch will cost more than it will cost to make a batch of 958 gallons.

Late in 1917 the first departments were issued orders for production quantities that were determined mathematically.

During the year 1917 the production of the plant was handled in 25,633 batches with a labor force of 554. Since 1917 the annual output of the plant has very materially increased. In 1928 the increased output was handled in 13,453 batches with a labor force of 482.

A force of about 23 persons carries on the routine detail of the Planning Department, which department has been put into operation since 1917. The Planning Department also operates the perpetual inventory records of finished stock. The work done by the Planning Department is deemed practically indispensable, but the cost of maintaining it would be very substantially more than present costs if production quantities had not greatly reduced the number of operations that have to be planned. Whether this department could function properly at a reasonable cost without economic production quantities is a question.

Automatic materials-handling equipment has reduced trucking to an absolute minimum. This mechanical handling, as well as machine bottling, gang bottling, and machine labeling, has greatly reduced the costs of the various operations that they do. Certainly to revert to 25,000 batches per year would cause a greatly reduced volume of work that could be handled by this equipment, and consequently reduce the profit from the investment in these devices. It is quite probable that, in many cases, a sufficient return to warrant the investments in these devices could not be estimated if it were not for the reduced number and the consequent increased sizes of the runs that are now made.

During the past five years the inventory of raw materials has been reduced 21½ per cent by taking advantage of conditions that were brought about by larger and less frequent batches or runs of staple products. Larger and less frequent batches of staple products suggested scheduling the production of these items in advance, in order that raw-material purchases could be scheduled to arrive just in time to meet the production schedules. The average inventory of raw materials in 1928 was $185,000 less than it would have been at the same rate of turnover as was experienced in 1923. This $185,000 has virtually been extracted from the business as an indirect result of economic production quantities.

During the year of 1917 the finished-stock account was turned three and two-thirds times. During 1928 it was turned four and one-third times. While merely reducing the number of batches to be processed per year would have gained some of the advantages mentioned in preceding paragraphs, to gain an increase in turnover of finished stock at the same time indicates that regulation of batch quantities has followed the principle of production at minimum cost.

To sum up, economic production quantities have afforded, or have assisted in affording, the following advantages to Eli Lilly and Company:

1 Considerably more production with 13,453 batches in 1928 than with 25,633 batches in 1917.

2 Considerably more production with a labor force of 482 in 1928 than with one of 554 in 1917.

3 Planning-Department supervision of production at reasonable cost.

4 Increase in application of mechanical handling of materials.

5 A reduction of 21½ per cent in raw-material inventory.

---

[1] Supervisor of Materials, Eli Lilly & Co.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

6 An increase in turnover of finished-stock account from three and two-thirds times per year to four and one-third times.

It would be quite impossible to designate a specific cause as being responsible for any of the six advantages listed above. A progressive management is constantly directing efforts toward the accomplishment of these six, as well as many other objectives, and it is undoubtedly true that the application of the principle of economic production quantities has contributed its share toward making these economies possible.

Some Cost-Accounting Problems

It would be very convenient if unit costs of record in the Cost Department could be used directly in the formulas for the determination of economic production quantities. But the cost plan was not designed to furnish unit costs for this particular purpose. Consequently there were numerous adjustments to be made in costs before they could be used.

The cost plan furnishes a unit cost of production for each batch of merchandise processed. This unit cost is broken down into a unit material cost and a unit processing cost. Burden is included in the latter.

The burden includes the cost of all non-productive departments, such costs in productive departments as changes in equipment between runs, and certain preliminary steps in the actual production. It increases the departmental costing rate per machine-hour or per labor-hour.

Following are some of the items of costs which are included in burden, although each item represents a practically constant cost per batch, regardless of the number of units to be produced in the batch.

1 Preparation of complete data on stock and sales to serve as notice that stocks must be replenished.

2 Blue-printing and registration of the production order.

3 Adjustments to perpetual-inventory records for raw materials to be used.

4 Weighing, checking, and verifying raw materials in the stock room.

5 Scheduling production by the Planning Department.

6 Checking or assaying the finished product.

7 Calculation of the bottling and finishing orders.

An hour of time spent on the operations listed is just as expensive as an hour of labor in a production department. These costs cannot be carried as overhead charges into an expression of unit cost if this expression is to be differentiated to determine the batch size that will give a minimum unit-production cost.

The cost data for use in the formulas for determining economic production quantities were obtained by adjusting the unit labor cost of record. Such elements of this cost of record as are shown above were introduced into the total-cost expression as a series of costs per batch. The unit labor cost of record was reduced to compensate for those component parts of this cost that had been introduced, in some other manner, into the total-cost expression. The remainder of the unit labor cost was then used as the unit cost of the actual production. In this way as much use as possible was made of the existing record of costs.

For a number of years it was not possible to determine economic production quantities for a line of items made in one large department. The items produced in this department were quite varied in nature. Some were finished in one day, while others took five weeks. The largest equipment in the department would handle 100 times the quantities that the smallest equipment would handle.

The Cost Department could not determine a set of rates that would cost all these products fairly. Several plans were tried out. Records over six or twelve months would be accumulated, then an attempt to use the costs in the formulas would prove the data to be unsuitable for use.

A very detailed study of equipment and costing rates was finally agreed upon as a possible source of a solution. This was carried out and a satisfactory cost plan resulted.

After sufficient cost data were accumulated the formulas for economic production quantities were derived. Calculations employing the new formulas showed that with less than $3500 investment in new equipment, savings could be effected that would more than justify the expenditure. The equipment was ordered promptly and installed. As a result the batch sizes of 155 items were increased.

Some of the 155 items have not yet been produced since the revision in batch sizes. However, during the first seven months of 1929 the costs in this department, including overhead charges, represent an annual saving of $11,950. The annual saving will probably reach $15,000 when the full benefit of the change in equipment is realized.

While it took a number of years to work out this problem, which was essentially a problem in accounting, the results have justified the effort.

The experience of Eli Lilly and Company with the application of the principles of economic production quantities indicates that it is just as necessary to study the cost-accounting system as it is to study the problems of the production departments. In fact the cost-accounting problems have been more difficult of solution than the production problems.

MAN-52-2b

Use of Economic Manufacturing Quantities

Obstacles Encountered in Introducing Mathematical Formulas for Economic Manufacturing Quantities—Lot Sizes

By ROBERT W. KENT,[1] BOSTON, MASS.

For the sake of establishing better manufacturing procedure, the author points out methods for determining how much to manufacture of a particular item or part at one time or in one lot. He discusses what is meant by economic manufacturing quantities, the aid toward increasing profits that comes from use of proper formulas, and states that minimum economic manufacturing cost can be obtained only through application of the principles made use of in developing a proper formula to fit each specific case.

IT IS the purpose of this paper to encourage the use of scientific and mathematical development in effecting manufacturing economies through effectively determining "how much" to manufacture, of a given item or part, at one time or in one lot.

Formulas are available that will prove valuable if used. It is true that attempts to understand them may prove discouraging unless one is either very patient or of rather above-average mathematical cleverness. Successful and practical manufacturing executives do not, in the author's experience, usually develop the nimbleness in transposing concrete facts and experience into abstract formulas that is necessary to rapidly digest and "become sold on" the practicability of using a lot of x's, y's, and k's to tell them how much should be manufactured at one time. Neither are they usually very deeply impressed by a lot of modernistic appearing curves or plots or by tabulations of untold quantities of figures.

A successful manufacturer is usually very apt to justly fear anything that savors of mystery or magic in any form. Furthermore, anything not readily subject to proof or anything involving complications of any kind is apt to hide errors, and factory procedure, to be successful, needs to be as foolproof as possible. Obscurity of any kind reduces fool-proofness. Since the average manufacturing executive does not appear to have sufficient mathematical mental agility to clearly, thoroughly, and readily grasp the development of formulas for mathematical determination of economic production lots or manufacturing quantities, he should prepare himself to settle down and really seriously and patiently set about understanding how the particular formula recommended for his use was derived. It may be that he must accept some of the mathematics on faith, but he at least should have explained to him the factors used and why, and he should substantiate them.

Circumstances alter cases, and no one formula can be used universally. In this paper it is the endeavor to point out that, for the sake of establishing better manufacturing procedure, management will do well to take whatever time is necessary to assure itself that it fully comprehends, first, what is meant by economic manufacturing quantities, and, second, that using a formula that fits the individual case will aid in increasing profits, and, third, that minimum economic manufacturing cost can be obtained only through application of the principles made use of in developing a proper formula to fit a specific case.

The following is a summary of experience with the adoption of economic manufacturing quantities:

Making effective use of scientifically determined economic manufacturing quantities in the normal manufacturing establishment becomes the function of those delegated with the work of planning production or operating a production-control department, but is nevertheless the responsibility of management, as it is probably the only available method of knowing definitely that minimum consistent manufacturing costs are being maintained and that inventories are so controlled that minimum practical investment is tied up in them.

During the last fifteen years the author has spent a large portion of his time in work which involved the development or improvement of production-control methods, together with the introduction of such methods and making them operate. Production-control methods, as developed and installed by large numbers of industrial engineers, have ranged in their intricacy from the point at which they were entirely too cumbersome to meet the requirements of sufficiently economical operation to the point of simplicity to the extent of neglecting many known applications of science which probably were essential to making any production-control procedure sufficiently valuable to warrant its use.

Planning and controlling production is simply an element in the application of scientific management to industry. The development of scientific management itself has, without question, been seriously hindered by the fact that perfectly good, sound ideas of high-grade technicians have been offered to industry which, in general, was in so youthful a stage of development as to be entirely unable to understand, appreciate, or make use of perfectly sound but nevertheless advanced technique.

The author many years ago reached the conclusion that, in introducing scientific management methods, one of the prime requisites of success consisted of so regulating the dose to be given that all of the medicine would be effectively and completely absorbed. In other words, it appears essential that those who have delegated themselves to the job of introducing the application of science to industry must prepare themselves to be satisfied with accomplishment which falls far short of the goal which they are able to visualize as a result of their manipulation of basic scientific principles, mathematics, and the work of the technician in general.

It is believed that some of our most learned and accomplished disciples of scientific management have fallen far short in their accomplishment of results by not being willing to be satisfied with a 30 per cent accomplishment of the goal rather than 100 per cent accomplishment. Had these same capable and experienced technicians actually tried to accomplish only one-third of what they were able to visualize as being possible, then their service to mankind would have been greater than it has, from the fact that the 30 per cent accomplishment would have actually been realized.

For instance, in the application of scientific management grievous errors frequently have been made through applying

[1] Vice-President, Bigelow, Kent, Willard & Co., Inc. Mem. A.S.M.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

methods for the control of direct labor costs which involved increased indirect labor costs (clerical effort) to absurd degrees. Examples have arisen where the present-day work of the industrial engineer has been to undo the work of predecessor engineers, through simplifying clerical detail, in order that advantages gained might not be outweighed entirely through the burdensome indirect cost of carrying out the prescribed methods.

Just as errors have been made in applying methods involving excessive amounts of "red tape," frequently one meets with situations where excessive amounts of mechanical handling equipment have been applied, and, in considering the use of mathematical formulas for the determination of economic manufacturing quantities, danger exists in including in the formula certain factors which have no particular bearing on the specific case. For instance, a space factor, or space charge, is frequently included in a formula for economic manufacturing quantities, and applied even in cases where the particular factory under consideration is entirely overequipped with floor space. In fact, it is probable that the majority of manufacturing plants in operation today have floor space available perhaps 50 per cent in excess of their real requirements. Obviously, it is not basically sound to assume that inventory is accumulating a rental charge under such conditions.

The foregoing emphasizes the thought that the particular conditions encountered in any manufacturing situation must be carefully weighed and balanced against the particular mathematics and technique being applied.

All of this discussion may appear to be somewhat far from the subject of establishing economic manufacturing quantities. However, the author in the course of his experience has had several occasions arise where the use of mathematical formulas for the determination of proper quantities which should be manufactured at one time seemed desirable and essential, and he has, with varying degrees of success, actually made use of such formulas. Installations of methods involving the use of such formulas have proved reasonably successful in connection with the manufacture of hosiery and underwear, paper boxes, chairs, office furniture and equipment, and in connection with the manufacture of parts for office calculating equipment, electrical instruments, and many similar products.

The early reaction, in the author's experience, to the attempted use of scientifically determined economic manufacturing quantities was that, were the quantities mathematically established as the proper ones to manufacture at one time actually made use of, inventories increased to an extent which sound business judgment proved was dangerous. Hence, instances are known where economic quantities were carefully calculated and then arbitrarily quartered or halved in order that inventories might be kept within reason. It is probable that the reason for the necessity of thus reducing the quantities which mathematics had told should be used, lay in the many intangible things which it is so hard to anticipate, such as obsolescence due to sudden style changes, or obsolescence due to the development of new materials (as, for instance, the introduction of rayon into the textile industry as a whole).

It is possible also that in the past there has not been sufficiently appreciated the extent to which return on capital invested in industry should exceed the return on investment in sound negotiable securities. It is very common for members of the producing phases of industry to think more or less of 6 per cent as a definite interest rate to be used in all calculations that they make, whereas it is probable that return on investment in inventories, equipment, etc., used in industry might much more properly be figured at from 9 to 18 per cent, in order that investors in industry may be assured of an added income to warrant their taking the added risk of business over banking. It developed, for instance, that a very real cause of the necessity for halving or quartering manufacturing quantities as calculated through the use of formulas, in the author's early experience with them, was that too low an interest rate on investment and in inventory had been used. The modern economist, as well as the investment banker, in analyzing and diagnosing business situations, more or less accepts as standard the necessity for earning returns in excess of the 9 per cent referred to. The risks brought out through the possibility of changes and fluctations in material prices, obsolescence due to new developments, credit stringencies, or business depressions of any kind, require that planned returns should frequently be double normal attainable returns on negotiable securities. Is it not clear, then, that it is a fallacy to use such a figure as a 6 per cent interest rate in determining cost of carrying inventories? Even when the higher interest rates referred to are made use of in attempting to program operations, unforecasted happenings almost always reduce the return from that planned. It is believed that it is safe to accept as an axiom that business return on investment should be no less than one and one-half to three times the safe return to be realized on sound, marketable securities.

As we know, the preparation cost, or the cost of making ready the various necessary equipment to run a production order of a given quantity, preparing the necessary forms, handling order through the plant, etc., is one of the most influencing factors in mathematical determination of an economic manufacturing quantity. The fact that in many industries a large portion of this preparatory work is performed by foremen, subforemen or job bosses, elevator operators, clerks, office executives, and stores or warehouse clerks, who are generally accepted as an overhead expense, interferes with proper determination of full preparatory cost, and is also one of the difficulties encountered.

In making use of mathematical formulas for determining economic manufacturing quantities it is therefore essential that in many cases entire accounting methods be changed in order that total preparatory expense may be determined. To the technician the changing of age-old accounting methods to improved methods very rarely constitutes an insurmountable obstacle, especially once he is convinced that the old-time methods are inaccurate or improper. However, to the business executive the mere thought or suggestion of changing such methods may immediately result in a decision to waive all attempts at application of scientific management in this particular regard.

Without question, a large portion of expense which finds its way into general factory overhead or, perhaps more accurately, into factory indirect labor, is, it is believed, in the majority of our plants today, made up of items which might in very many cases be quite legitimately charged to preparing cost or cost of making ready to run production orders or lots.

Attempts to segregate properly these costs from actual indirect cost, which will result in continuous analysis of the time of these many-times-privileged individuals, may result in resistance to the methods being installed to an extent that is unpolitic. In more simple terms, much of the work which goes to make up the job of foremanship as it is now constituted consists very largely of make-ready effort and is in reality direct labor cost.

It is possible that enumeration of some of the impediments encountered in actual attempts to make use of formulas for determination of economic manufacturing quantities may be worthy of mention in that, in being prepared for an obstacle, the obstacle may be surmounted the more easily.

In attempting to establish bases for determining size of manufacturing quantities which may have been in use in the past in plants, it has almost always been surprising to find the lack of any real reasoning employed. Lots of 1000 units very fre-

quently will be found to have been used for manufacturing quantities, for no specific reason whatever. Quantities which will keep factory workers busily employed for one day's time, or one pay period's time, frequently seem to be in vogue. Quantities which will constitute a truckload or a trayload also seem to prevail as standards employed in determining size of manufacturing lots.

All of these, of course, seem ridiculous in that they present no consideration of the real cost involved nor the effect on cost of difference in the size of lots. Yet even with these crude methods of establishing manufacturing quantities, business has been performed in a profitable manner, with the result that extreme reluctance is encountered when suggesting any changes from the established procedure. Also, considerable work has been done in connection with the establishment of financial ratios (ratios of various balance sheet items) which attempt to dictate how large inventories in general should be. Considerable data are available, and business executives talk learnedly of what should be the rate of turnover of inventories. When manufacturing quantities are established, there also are established average inventory values for the particular items concerned, and the resultant effect of establishing scientific manufacturing quantities for all the items in the various lines of product is immediately seen on the inventory in total.

If one increases the size of manufacturing lots, naturally the inventories are increased to a degree that may be considered very dangerous indeed. Also, one complicates the clerical work involved in properly tracing or routing an order through a plant if the quantities become so large as to be impractically handled in single transportation units. If, on the other hand, one decreases the size of lots, there are immediately imposed more diligent planning and layout and set-up work on the foreman and his assistants, and here again is a change from past routine which naturally arouses antagonism.

Difficulties also are encountered in selecting the proper formula to fit the particular case at hand. Determination must be made as to whether one uses as factors in the formula the direct cost only or the total cost, with or without overhead, and whether these factors include items which are really independent of quantity. Also, consideration must be given to the factors involving cost of capital. Shall inventories only be included or shall work in process be included? Must operating space charges be included as factors, and must space charges for inventories be included? Consideration must be given to all of the foregoing and the situation be weighed and the proper solution arrived at fitting the particular case in hand. Changes in rate of demand, due to seasonal trends, also frequently make it necessary to re-calculate manufacturing quantities for different periods.

Experience has proved that, if sufficiently careful consideration is given to the particular application of the formula involved, very surprising economy may be effected, and occasions have arisen where entire factory management policies were advantageously changed as a result of making use of economic manufacturing quantities. It has been the purpose of this presentation of ideas to expound the theory that it is wise to be just as scientific as conditions and personnel encountered will permit. In other words, if one simplifies the procedure of arriving at economic manufacturing quantities sufficiently to insure acceptance of the practice, one may be more definitely assured of real accomplishment than if insisting on a more dogmatic application of mathematical data. The experience with which this paper treats may be summed up somewhat as follows: No sound rule-of-thumb procedure for determining how much to manufacture at one time has been encountered in a careful consideration of nearly one thousand manufacturing establishments. A sizable field for the effecting of economies through the application of a scientific procedure of determining how much to manufacture at one time very definitely exists. It is worth while to inject mathematics into this general problem even if some elements or factors which should be included are dispensed with to make the procedure more salable. Even in instances where such formulas, even lacking certain necessary elements, are used, advantages are gained in that various items going to make up inventories as a whole are brought relatively more nearly in balance. One very distinct advantage of making use of economic manufacturing quantities is that periods of peak production and sales are met much more easily, and the additional cost, due to changing sizes of manufacturing lots, can be definitely known. It is almost always true that in making use of economic manufacturing quantities cost-collection methods are radically improved. Overhead items are brought more definitely within control, and many advantages are thus gained which were not necessarily the objects in view when the methods were adopted.

An attempt has been made in the presentation of this paper to get away from an academic or scholastic presentation, in the hope that the virtue which so surely exists in the use of formulas for determination of manufacturing economic quantities may be more widely realized and use be made of them.

MAN-52-2c

Advantages Derived From the Simplification of the Fundamental Formulas for Economic Production Quantities

By FAIRFIELD E. RAYMOND,[1] CAMBRIDGE, MASS.

The paper seeks to demonstrate that a rapid and reliable method can be developed for application to the problems most frequently encountered in planning production schedules and controlling inventories. This method is stated to be more simple than the fundamental formula developed in the author's former paper on "Economic Production Quantities." Other advantages are gained from the simplified method.

IN PREPARING the paper[2] on "Economic Production Quantities" presented to the Society by the author in 1927, it was fully appreciated that the fundamental formula therein developed would be too complicated for direct application to the practical problems most commonly encountered in planning production schedules and controlling inventories. It was pointed out at that time, both in the paper itself and later during the discussion, that only after a thoroughgoing investigation of the basic factors entering into the determination of an economic production quantity could a suitable means for selecting simplified forms be evolved. In the light of recent developments it seems that the fundamental relationship has been sufficiently well established to warrant, at the present time, a study of this problem with particular regard to a simplification of the general form. Therefore, it will be the purpose of this paper to demonstrate that a rapid and reliable method can be developed, and that definite limits exist for governing the use of each form. Besides the advantages gained from a simplification of the method of determining an economic production quantity by means of which much of the implied calculations can be dispensed with, others of even greater importance can be attained.

First, a wide range in the size of any manufacturing lot can be established from the limits governing the simplified form which can be used to adjust production schedules, to account for fluctuations in the sales demand, and to offset errors arising from estimates or sales forecasts or from uncontrollable circumstances in the manufacturing operations.

Second, conservation of capital can be achieved by the production of a quantity much smaller than the apparent economic quantity, if the increase in cost due to the smaller lot size does not impair the normal profit expected in return from the sale of the article. In determining the permissible variation in production quantities it was found that considerable latitude can be obtained for a very slight increase in the minimum ultimate unit cost of any unit of production. If the production quantity calculated from a simplified form, which in all cases is greater than the economic quantity, is permissible for this reason, a quantity smaller than the economic quantity which does not exceed these same permissible limits can be used instead to better advantage, as the amount of working capital required for production in this case will be much less. Much criticism of the economic quantity method of production control has developed from the fact that an increased amount of capital was required to achieve the desired reduction in cost due to the ability to select accurately the economic lot size which in the end entirely offset the apparent gain to be thus derived. Now by the greater knowledge that is available as to the effect of the lot size upon the ultimate unit cost, a production quantity can be determined which should satisfy all situations.

Third, the savings which can be made as a result of improvements in design or the method of manufacture or by more accurate methods of production control can be determined for any case. An index of the change in cost for any two conditions of the same unit of production has been developed which may be used to compare one with another, without necessitating the actual determination of the various total cost items involved. This should be of considerable advantage to the process engineers and those responsible for the continuous improvement of manufacturing operations in general. All of these advantages can be realized by various methods of applying the chart accompanying the calculation sheets. The procedure for each case is fully described in the latter part of the paper.

Calculation Sheets—Selection of Simplified Forms

Before attempting to establish these principles supporting the proposed method of selection and limits of variation, attention will be called to the calculation sheets (given in Tables 1 and 2) which embody the results of this study. These sheets were prepared for use directly in any planning or production control department without requiring a particular knowledge of mathematics or a specialized engineering training, and have been divided into two parts, one of which is optional. The first, for general use, outlines the procedure for determining the simplified form applicable to any specific problem. The second provides means for establishing the maximum allowable limits of variation in production quantities from the ideal or economic quantity, for any problem, with due regard for the normal profit expected in return for the sale of such articles, and provides a check as well upon the method of selection in Part I (Table 2) by the determination of the permissible variation in the answer for a given form.

It should be noted that the last section can be omitted when the probable limits of usefulness for a given case have been previously determined or assumed from experience to warrant the use of the form selected without further computations. In fact, the limits obtained in the second part, when once calculated, will be applicable as long as there is no radical change in the product or process, and will have to be recalculated only when a new form is selected, should the form index show that the arbitrary limits used in the first are no longer reliable.

The proposed method has been so arranged that the minimum amount of figuring is required; in fact, the major part of the

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

work in the first section, which is most commonly used, may be accomplished by a rapid inspection of certain index ratios, the values of which may be calculated with sufficient accuracy through the use of a slide rule. Moreover, only two significant figures need be used in the value of any item to yield entirely satisfactory results. Again, if a new form has to be selected

TABLE 1 INTERPRETATION OF DATA

Item	Definitions	Symbols
1	*Unit Material Cost* (in dollars per piece). (This is the total unit cost of the material used in making the part taken at the time it enters the process or is set down at the first operation.)	m
2	*Unit Production Cost* (in dollars per piece). (Add to item 1 all labor and overhead charges incurred in fabricating or assembly operations on the piece, except charges arising from the set-up and dismantling of the machines which perform these operations, and charges for production control entered under item 3, as well as such charges appearing in item 8; both of which should be removed from overhead, distributed upon operating time, if used.)	c'
3	*Preparation Cost* (in dollars per lot). (This item includes total labor and overhead charges involved in setting up the machines for fabrication of the parts or the assembly line, and dismantling the set-ups after parts are produced, as well as the cost of writing and issuing the production order, production control costs, or any charges directly pertaining to the "lot" and not dependent upon the quantity produced in the lot.)	F
4	*Unit Production Time* (*a decimal figure in days*)[1]. (Determine for each operation the time consumed to perform the operation for one piece. If this is determined on an hourly basis it should be divided by the average hours per working day in the week. If the production rate in pieces per day is known, the reciprocal of the production rate per day for each operation. Add the resulting decimal figures together to obtain the unit production time for all operations.)	t
5	*Consumption Rate* (pieces per year)[2]. (Obtain the most reliable estimate possible for the total consumption of this part or assembly, whichever the case may be, for the current year.)	Y_a
6	*Interest Rate* (in per cent per year)[2]. (Obtain the figure for the interest rate in per cent per year which ordinarily would be paid on borrowed capital and which would be used to compute the cost of capital employed.)	i
7	*Space Charge* (dollars per sq. ft. per year)[2]. (Add together all charges resulting from taxes, insurance, maintenance, depreciation, interest, etc., for the building, equipment and fixtures, heat, light, etc., accruing during the year to the finished stores section, and divide the total for the year by the total floor area for all spaces covered by these charges.)	v
8	*Average Height* to which storage is permitted in finished parts stores (in feet). (This height should be measured from the floor to the top of the highest bin, which in all probability will be constant for a given stores space, or if no bins are provided this will be the height to which finished parts may be conveniently stacked one upon another, or one container upon another.)	h
9	*Unit Storage Space Required* (cu. ft. per piece). (This should represent the overall space required per article with due allowance for clearances, voids in stacking, handling space, etc. A representative figure may be obtained by measuring the space occupied by a number of these articles as they lie in storage and then reducing it to a unit value.)	B
	(Optional Data, for Use Only in Special Cases)	
10	*Rate of Delivery to Stores* (pieces per year)[2]. (When the manufacturing and sales periods overlap, determine the number of articles per day which can be removed from the process as fast as the fabrication or assembly of each is completed. If no overlap occurs the factor $k_p = 0$ should be used.)	D
11	*Number of Batches per Lot*. (When a lot is divided into batches for ease in processing. n should represent the number of subdivisions, and if the lot can be processed continuously, $n = 1/0$ or $kp = 1$.)	n

[1] If the value for the consumption rate (S) is not to be expressed in pieces per day when inserted in any one of the formulas, but as pieces per week, or per month, or per year, the value for t in days should be divided by the number of working days per week, per month, or per year, as the case may be.

[2] If it is the practice in any company to express the rate of consumption in terms other than pieces per year such as pieces per month, week, or day, the values as specified in items 5, 6, 7, and 10 should be divided by the number of months, weeks, or days normally worked in a year, overtime omitted, as the case may be.

as a result of a marked change in the sales demand Y_a, only the ratio R_w will have to be recalculated. However, if it was brought about through a change in the process, both the ratios R_v and R_w will have to be recalculated because the unit production cost c' will naturally be altered and one or more of the terms D, t, and k_p will have new values. For ordinary corrections in the labor or burden distribution rates no new form or alteration in the production quantities will be needed, but if

TABLE 2

Part I Form for the Selection of Simplified Expressions for the Economic Production Quantity or the Minimum Cost Quantity

Procedure (obtain data from Table 1)	This space is to be used for computations
Item 1 Divide v by i and multiply by $2/h$	$= \frac{\cdots}{\cdots} \times \frac{2}{\cdots} = \cdots$
Item 1 is a constant for all problems in a given plant and need be calculated but once	
Item 2 Divide B by c'	$= \frac{\cdots}{\cdots} = \cdots$
Item 3 Multiply item 1 by item 2	$= \cdots \times \cdots = \cdots = \cdots = R_v$
Item 4 Subtract k_p/D from $(1/Y_a)$	$= \frac{1}{\cdots} - \frac{\cdots}{\cdots} = \cdots$
where $k_p = 0$ for non-continuous production; $k_p = 1$ for semi-continuous production; $k_p = (1 - 1/n)$ for batch production	
(See text pages for references, and see note 1 below.)	
Item 5 Divide t by item 4	$= \frac{\cdots}{\cdots} = \cdots$
Item 6 Divide m by c' and add one	$= \frac{\cdots}{\cdots} + 1 = \cdots$
Item 7 Multiply item 5 by item 6	$= \cdots \times \cdots \quad \cdots = \cdots = R_w$
Item 8 (A constant for all problems)	$1.0 = R_s$
Item 9 Add item 3, item 7, and item 8	$= \cdots + \cdots + 1 = \cdots = R_c$

Item 10 (*a*) Select, by inspection, any one (or two if necessary) of the index ratios (items 3, 7, or 8) so that the total value of those selected will be at least $^2/_3$ the value of the index ratio R_c (item 9).
(*b*) Check off here the index ratios selected $R_v(\ )$, $R_w(\ )$, $R_s(\ )$.

Item 11 *The Simplified Form*
Place in the denominator of the simplified form the following expressions according to the index ratios checked above

If R_v is chosen, use $\frac{v \cdot B}{h} \cdot \left[1 - \frac{Y_a}{D}\left(1 - \frac{1}{n}\right)\right]$

If R_w is chosen, use $\left(\frac{m + c'}{2}\right) \cdot Y_a \cdot t \cdot i$

If R_s is chosen, use $\frac{c' \cdot i}{2}\left[1 - \frac{Y_a}{D}\left(1 - \frac{1}{n}\right)\right]$

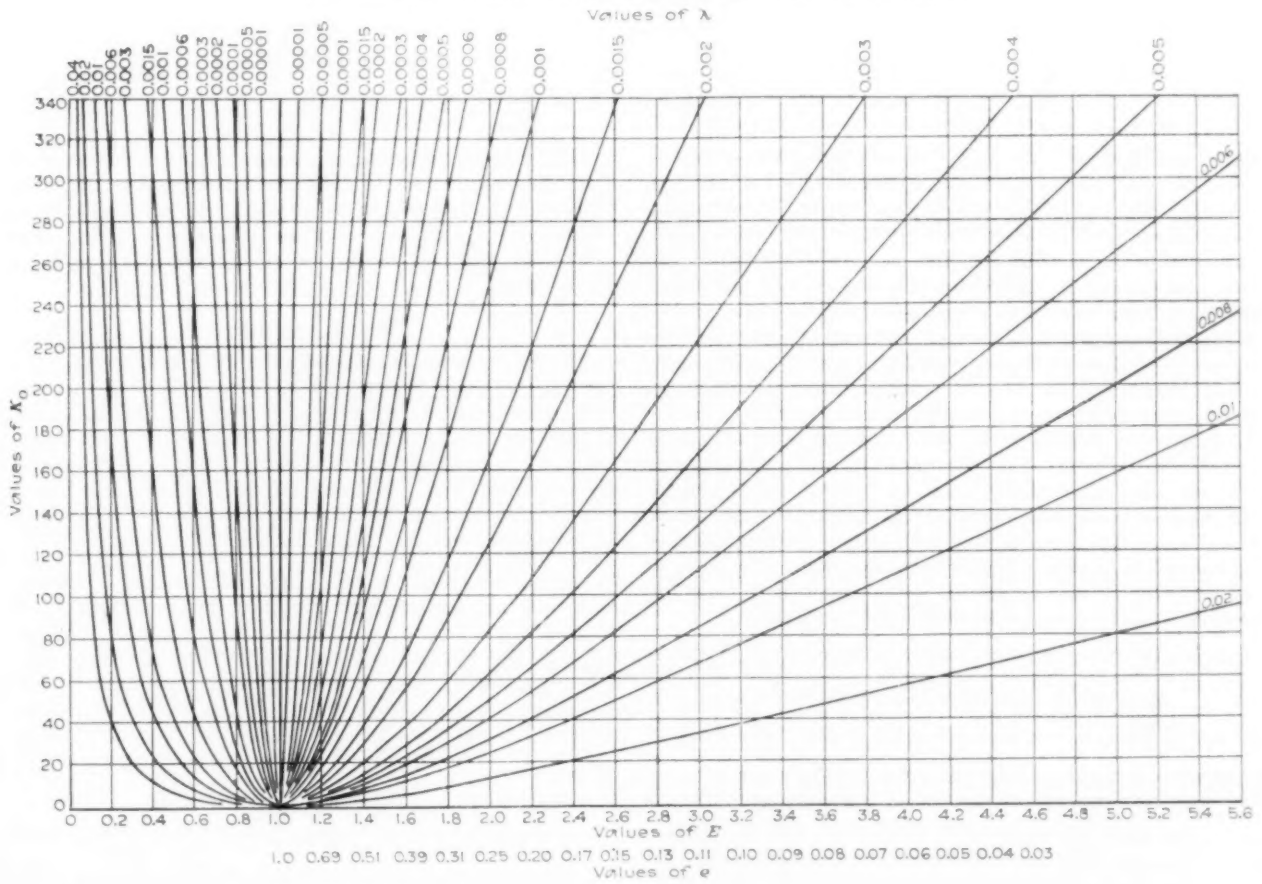
So that the economic production quantity $= \sqrt{\frac{F \cdot Y_a}{(?) + (?) + (?)}}$

where F = the total preparation charges in dollars.

[1] If item 4 $\times$ Y_a = 0.9 or greater, omit the parenthesis $1 - \frac{Y_a}{D}\left(1 - \frac{1}{n}\right)$ from any element where it may appear.

TABLE 3

Part II (Optional) Form for Determining the Value of the Problem Index and the Allowable Variation for Simplified Expressions (Using values for items given in Part I and data from Table 4)



Procedure	This space to be used for computations
Item 12 Divide item 7 by item 9	$= \frac{\cdots}{\cdots} = \cdots$
Item 13 Divide c' by F	$= \frac{\cdots}{\cdots} = \cdots$
Item 14 Multiply item 12 by item 13	$= \cdots \times \cdots = \cdots$
Item 15 Multiply i by t by item 6 by 2	$= \cdots \times \cdots \times \cdots \times 2 = \cdots$
Item 16 Divide item 14 by item 15	$= \frac{\cdots}{\cdots} = \cdots$
Item 17 Find square root of item 16	$= \sqrt{\cdots} = \cdots$
Item 18 Add one to item 17	$= 1 + \cdots = \cdots = K_o$
Item 19 (Refer to the figure in Table 4) Select curve in right-hand portion of chart for an allowable per cent increase λ_d in unit cost over the minimum cost and locate point on bottom scale below point of intersection of the appropriate curve for λ_d with the horizontal line drawn through the value of K_o (item 18) on the vertical scale. Read off the decimal figure for this point, which will be the value for the form index. The value obtained from item 19 may be used in place of the ratio $^2/_3$ employed in item 10 (Part I) for selecting the appropriate simplified expression, if greater accuracy is desired, or	$= \cdots = c$
Item 20 Multiply item 9 by item 19	$= \cdots \times \cdots = \cdots = R$
Item 21 Then, turning to Part I, select the index ratio (or any group of two) which has a value greater than that for R given in item 20 and check these off in the appropriate spaces provided in section *b* of item 10. The appropriate simplified form will be obtained as usual from item 11.	
Item 22 Referring again to Table 4, read off the values of the maximum limit of variation in production quantities.	$= \cdots = E_m$
the minimum limit of variation in production quantities which lie directly below the points of intersection of the curves representing λ_d to the right and left, respectively, with the horizontal line through K_o = (item 18).	$= \cdots = E_m$

the correction is of considerable magnitude the ratio R_e may be recalculated to test the effect of such a change. The application of the calculation sheets to a specific problem has been illustrated by an example, worked out in detail, at the end of this paper.

Advantages Accruing From the Use of the Calculation Sheets

At first glance, it may seem that an undue amount of effort is required to simplify the original complex expression, in addition to the work of solving for the production quantity. However, it must be remembered that only the first section of the calculation sheets is required for the selection of the simplified form, and that the remaining sections provide valuable information which could be obtained in no other way. In fact, the practical limits of variation allowable in the arrangement and control of production schedules thus established, in all probability, will preclude the necessity of having to recalculate the economic quantity or minimum-stock requirements to account for ordinary fluctuations in business until some decided change in the situation has occurred. Accordingly, is it not wiser to make these additional computations once for all, if other computations, periodically made, can be eliminated and thereby permit a simplification of departmental routine as well?

TABLE 4 CHART FOR DETERMINING THE ALLOWABLE VARIATION e IN THE DATA, THE LIMITS OF THE ECONOMIC RANGE E_M AND E_M FOR PRODUCTION QUANTITIES, AND THE SAVINGS ACCRUING FROM IMPROVED METHODS OF PRODUCTION CONTROL AND THE CONSERVATION OF CAPITAL

Method of Simplification

If this be true, much can be gained by demonstrating that a sound mathematical basis underlies the proposed methods, because when this is once established, further recourse to the theory will not be necessary, as the procedure thus developed will automatically produce the desired results by indicating directly the appropriate form for use in any case. Briefly, it may be stated that the simplification of the general form was achieved, first by justifying the choice of that type of solution for the economic production quantity which could be most easily simplified; second, by eliminating those factors which apply only in extraordinary cases; third, by providing means for selecting for use in the desired simplified expression only those elements contained in the general expression which have a distinct bearing upon a specific problem; fourth, by indicating where constant values may be introduced for terms having a general significance and how the remaining terms may be grouped so as to shorten the labor of calculation; fifth, by determining the allowable variation in the data consistent with the permissible variation in the answer for any particular form used; and sixth, by establishing a maximum limit for the permissible variation in the answer, depending upon the conditions surrounding a given problem and the loss incurred by the use of production quantities varying to some degree from the ideal or economic quantity. The remainder of this paper will be devoted to a detailed discusion of these factors, and no attempt will be made here to discuss further the derivation of the fundamental formula, as it is assumed that its general form would not be seriously changed by additional discussion or a more extended analysis.

Approximate Solution

It should be remembered, to begin with, that the economic production quantity can be solved for mathematically in two ways, one exact and one approximate. Upon reference to the introduction of the original paper, where the two types of solution have been illustrated, it will be immediately evident that the form yielding an exact solution is much too complicated in its structure to lend itself readily to simplification, especially when compared with the simpler form for the approximate solution. The use of the exact solution brings to mind an extended controversy which has long been extant among accountants, over the use of interest as an item of cost, because in this case where the ultimate unit cost is employed as the value of articles in stock for inventory purposes, the cost of capital, based upon the current interest rate is introduced into this value. As a result an investment charge accrues not only from the capital employed in inventories but also from the cost of this capital. Compounding these costs in this manner is not recognized by accountants at the present time as representative of the true financial situation, and they prefer to post the cost of such capital to the general cost of doing business rather than inflate inventories with a charge which they believe to be of a corporate nature. On the other hand the accounting method underlying the approximate solution conforms directly with current practice and this reason alone is sufficient to justify the use of this method of determining an economic production quantity. Moreover, it was pointed out that the error resulting from the use of the approximate form would be negligible in all cases except where the production quantities were small in proportion to the fixed or preparation charges they may have to bear,[3] and that the time and labor of calculation saved by its use will far outweigh the slight increase in accuracy obtained from the use of the exact form, as the advantages gained from the more complicated expression are entirely of a hypothetical nature. Therefore, as the first step toward simplification the expression for the approximate solution will be adopted, in which case[4]

$$Q_e = \sqrt{\frac{F \cdot Y_a}{c' \cdot i \cdot \left[\frac{1}{2} - \frac{Y_a}{D} \cdot \left(\frac{1 - 1/n}{2}\right)\right] + \left(\frac{m + c'}{2}\right) \cdot i \cdot Y_a \cdot t + \frac{v \cdot B \cdot}{h}\left[1 - \frac{Y_a}{D} \cdot \left(1 - \frac{1}{n}\right)\right]}} \quad \ldots\ldots [2]$$

This is the form published in the Management Handbook Data No. 102, revised to meet the new interpretation of the production rate, referred to in footnote 4. In fact, if a case arises wherein any of these factors must be considered, it will in all probability, require the use of the unsimplified expression, Equation [1].

Major Elements

The third step toward simplification will consist in a study of the general form of Equation [2] in order to determine the relative importance of the various major elements in its composition, and to eliminate such elements as have little or no effect upon the final results when the conditions governing a specific problem are fully understood. To facilitate the discussion and provide a suitable basis for comparison, Equation [2] will be rewritten so as to show only the major elements, as follows:

$$Q_e = \sqrt{\frac{K_F}{K'_s + K'_w + K'_v}} \quad \ldots\ldots [3]$$

$$Q_e = \sqrt{\frac{F \cdot \{2\Theta Y_a - \Delta \cdot [\Theta Y_a + Y'_r (f - 1) \cdot i]\}}{c'i \cdot \left[(k + f - 1) \cdot \Delta - \Theta \frac{Y_a}{D}\left(\frac{1 - 1/n}{2}\right)\right] + \left(\frac{m + c'}{2}\right) \cdot i \cdot \Theta \cdot Y_a \cdot t + \frac{vB\Delta}{h} \cdot \left[1 - \frac{Y_a}{D}\left(1 - \frac{1}{n}\right)\right]}} \quad \ldots\ldots [1]$$

where Q_e = the economic production quantity (pieces)
f = reserve stock factor (see original paper)
Δ = coefficient of deterioration (see original paper)
Θ = coefficient of obsolescence (see original paper)
Y'_r = the total sales up to the order point in the previous sales turnover period (pieces)

All other terms in the equation have been fully described in Table 1.

Elimination of Extraordinary Factors

As the second step toward simplification, it will be assumed under ordinary conditions of business, first, that the rate of consumption or sales will remain approximately uniform for any given period; second, that the finished product will be sufficiently stable to permit a total disregard of the factors of obsolescence θ and deterioration Δ;[5] third, that for the reasons stated in the original paper, the reserve stock coefficient f has no practical value and can be omitted. As a result of the first assumption Y_a will become a constant, there being no need for any consideration of variable demand, and the stock coefficient k may be given the value of $^1/_2$. Similarly, when the factor f is unity, the term Y'_r will drop out. Accordingly a new formula can be written, where

where
K_F = all items in the numerator = $F \cdot Y_a$
K'_s = investment charge element for articles in stores $= c' \cdot i \cdot \left[\frac{1}{2} - \frac{Y_a}{D}\frac{(1 - 1/n)}{2}\right]$
K'_w = investment charge element for work in process $= \left(\frac{m + c'}{2}\right) \cdot i \cdot Y_a \cdot t$
K'_v = space charge element for articles in stores $= \frac{v \cdot B \cdot}{h}\left[1 - \frac{Y_a}{D}\left(1 - \frac{1}{n}\right)\right]$

Likewise, the typical form for all the various simplified expressions, obtainable through the application of the method outlined in Part I of the calculation sheets, can be written in a similar

[3] The practical limits of use for the approximate solution are excellently discussed in an article by Gordon Pennington, published in *Manufacturing Industries*, March, 1927.

[4] Owing to a change in the interpretation of the production rate from that used in original paper, the symbol P has been removed and the symbols D and t have been inserted in place of it. This change necessitates removing P from the numerator and dispenses with the need for the factor a' in the work in process element. To clarify this element further the terms $(m + c')/2$ have been used in place of $c'k_p$ and the repetition of the term i has been corrected, as it should appear but once in either of the first two elements. Moreover, the term h has been introduced in the third element to remove any uncertainty in the determination of the values for v and B when the space B occupied by any article in stores is expressed in equivalent square feet rather than in cubic feet as normally.

[5] When the factors Δ and θ are to be disregarded, the value of unity should be assigned to each.

manner, as illustrated in Table 5, Part I. Thus the necessity for writing out such expressions in full each time they are referred to can be avoided, and then, when one of these forms is selected for a given problem, it will be a simple matter to substitute the exact expressions, as given, for the particular elements contained therein. Another device may be introduced at this point to assist in designating in a given case, the form required for calculating a value for the production quantity Q by attaching a characteristic subscript to the general symbol (as, for instance, Q_u equals any uneconomic production quantity varying to some degree from the economic production quantity Q_e). Similarly, Q_{sv} would indicate that this quantity is determined by the use of the storage and space charge elements in the denominator. It should be noted that the numerator in all the simplified expressions is the same and is represented by the element K_F.

TABLE 5

Part I Simplified forms	Part II Expressions for e
$Q_{sw} = \sqrt{\frac{K_F}{K'_s + K'_w}}$	$e_{sw} = \frac{K'_s + K'_w}{K'_c}$
$Q_{sv} = \sqrt{\frac{K_F}{K'_s + K'_v}}$	$e_{sv} = \frac{K'_s + K'_v}{K'_c}$
$Q_{wv} = \sqrt{\frac{K_F}{K'_w + K'_v}}$	$e_{wv} = \frac{K'_w + K'_v}{K'_c}$
$Q_s = \sqrt{\frac{K_F}{K'_s}}$	$e_s = \frac{K'_s}{K'_c}$
$Q_w = \sqrt{\frac{K_F}{K'_w}}$	$e_w = \frac{K'_w}{K'_c}$
$Q_v = \sqrt{\frac{K_F}{K'_v}}$	$e_v = \frac{K'_v}{K'_c}$

Coefficient of Permissible Variation in Production Quantities

From a comparison of the proposed forms given in Table 5, it is evident that the denominator for any one of the simplified forms will have a value smaller than that for the general form, because one or two of the major elements have been omitted. This means that any value for a production quantity Q_u obtained from one of the simplified forms will be greater than the value for the economic production quantity Q_e in the same problem. Consequently, this discrepancy in results, if evaluated, will serve as an index or measure for controlling the selection of the most suitable simplified form for a specific problem, provided that a definite maximum permissible limit of variation E_M[6] can be established to represent the existing conditions. Accordingly the coefficient E will be introduced to signify the permissible variation in the answer for a given case, the value of which can be determined from the equation

$$E = Q_u/Q_e \quad \ldots\ldots [4]$$

Coefficient of Allowable Variation in the Data

Furthermore, if the coefficient E is to be of any real value, its relation to the allowable variation in the data, resulting from the choice of elements for any simplified form, must be definitely established. Accordingly, if K' is allowed to represent any one, or a group of two, major elements used in the denominator and if

$$K'_c = K'_s + K'_w + K'_v$$

(i.e., the denominator of the general form), the coefficient e of allowable variation in the data may be expressed as

$$e = \frac{K'}{K'_c} \quad \ldots\ldots [5]$$

[6] The appropriate value for E_M for any problem can be obtained from Equation [27] or Table 4.

and then

$$Q_u = \sqrt{\frac{K_F}{K'}} \qquad \text{or} \qquad \sqrt{\frac{K_F}{e \cdot K'_c}}$$

Similarly if

$$Q_e = \sqrt{\frac{K_F}{K'_c}}$$

$$E = \frac{1}{\sqrt{e}}$$

and

$$e = \frac{1}{E^2} \quad \ldots\ldots [6]$$

Therefore, if E, in Equation [6] be replaced by its limiting value E_M, there will be some value for e which cannot be exceeded, and if a value for e is calculated from Equation [5] for various simplified forms and compared with the value for e from Equation [6], the most suitable form may be reliably selected. To illustrate how the various elements contained in each form may be represented by the coefficient e, the specific expression for e in each case has been included in Table 5, Part II. Moreover, at this point attention should be called to the fact that for a given variation in the answer a much larger variation in the data will be allowable, because e depends upon the reciprocal of E^2. As a result, greater latitude is permitted in the choice of a simplified form than could be if e were merely inversely proportional to E.

Index Ratios

If it were actually necessary to calculate the values for e in each case from the expressions given, little saving could be realized from the use of simplified forms. However, this can be avoided by employing a series of index ratios having a common denominator, each one of which will represent the relative importance of a particular element.

Accordingly let

$R_v = \frac{K'_v}{K'_s}$ and be the index for the space charge element K'_v

$R_w = \frac{K'_w}{K'_s}$ and be the index for the investment charge element K'_w on work in process

$R_s = \frac{K'_s}{K'_s}$ (a constant) and be the index for the investment charge element K'_s on articles in stores

$R_c = \frac{K'_c}{K'_s} = R_v + R_w + R_s$ and be the index for the denominator of the complete expression containing all elements.

Now upon substituting the full expressions for each one of these elements in these ratios, it will be found that certain groups of terms will cancel out, leaving only the important factors, so that the resulting simple expressions for these ratios may be used as a basis for the desired method of selection without involving any great amount of calculation, as previously discussed in connection with the calculation sheets. Hence,

$$R_v = \rho \cdot \frac{B}{c'} \qquad \text{where } = \rho \frac{v \cdot 2}{i \cdot h}$$

$$R_w = \frac{\left(1 + \frac{m}{c}\right) \cdot t}{\left(\frac{1}{Y_a} - \frac{k_p}{D}\right)} \qquad \text{where } k_p = (1 - 1/n)$$

$$R_s = 1.0$$

Two new terms have been introduced at this point to account for certain factors which are constant under specified conditions. The first, the plant ratio ρ is a constant for any plant as the terms v, i, and h have the same respective values regardless of the problem, and the second, the process factor k_p has a definite value for each type of process,[7] as follows:

For continuous production $k_p = \infty = \frac{1}{0}$

For semi-continuous production $k_p = 1$

For non-continuous production $k_p = 0$

For batch production $k_p = \left(1 - \frac{1}{n}\right)$

where n = the number of batches making up one process lot.

Method of Selection

Now that the identity of the index ratios of R_v, R_w, R_s, and R_c have been established, it is a simple matter to show how the resulting coefficient e for the variation in the data is obtained for use in the method of selection. If

$$e = \frac{K'}{K'_c}$$ by definition from Equation [5] and

R is allowed to represent the numerical value of any single index ratio or the combination of any two, in the same way that K' represents any desired grouping of the major elements, then

$$e = \frac{R}{R_c} \quad \ldots\ldots [7]$$

because

$$R = \frac{K'}{K'_s}$$

and

$$R_c = \frac{K'_c}{K'_s}$$

and the ratio R/R_c or e can be designated as the "form index."

By transposing this expression, it will be found that

$$R = e \cdot R_c \quad \ldots\ldots [8]$$

and if a value for e is used in this equation, which depends upon the maximum permissible limit E_M of variation (see Equation [6]), the resulting value for R will be the index for the elements that will be appropriate for use in the denominator of the desired simplified form. Accordingly, each index ratio should be compared, by inspection, with the general index R, and the one having a value slightly in excess of the value for R will indicate the particular element that should be retained in the denominator of Equation [3]. In case no single index ratio meets this requirement, some combination of two can be found that will, and then the two elements represented by these ratios will have to be used instead.

However, under ordinary conditions it has been found from experience that when the form index e has a value of approximately 0.666, the resulting simplified expressions will yield production quantities that will be quite satisfactory. Therefore, in drawing up the first part of the calculation sheets, an arbitrary index e_s, equal to 0.666 (or $^2/_3$), was introduced, in order to simplify the method and to dispense with the necessity of determining E_M and the limiting values for e and R for every problem. Of course, if any peculiar condition exists which may give sufficient cause to doubt the reliability of this assumption, these limiting values may be determined in advance. For this reason Part II of the calculation sheets has been prepared, but its use has been allowed to remain optional.

[7] For a more complete definition of each type of process reference should be made to that specific section of the original paper.

Short-Cut Method for Determining the Economic Production Quantity

If the actual variation from the true economic production quantity Q_e for any production quantity Q_u, obtained from one of the simplified forms, is measured by the coefficient E (see Equation [4]), the value for which depends upon the appropriate index e for the form used, it is quite possible to determine the correct value for Q_e directly from Q_u and thereby avoid recourse to the general expression (Equation [2]) for its solution, because

$$Q_e = \frac{Q_u}{E} \quad \text{(or)} \quad = \sqrt{e} \cdot Q_u$$

whereupon

$$Q_e = \sqrt{\frac{e \cdot K_F}{K'}} \quad \ldots\ldots [9]$$

or

$$= \sqrt{e_s \cdot \frac{K_F}{K'_s}}$$

$$= \sqrt{e_w \cdot \frac{K_F}{K'_w}}, \text{ etc.} \quad \ldots\ldots [10]$$

or, in fact, any other combination of elements. This can be carried still further if desired so that

$$Q_e = \sqrt{\frac{R}{R_c} \cdot \frac{K_F}{K'}}$$

by using the general terms R and K'.

The question may arise as to the need for the calculation sheets if such a short cut is available for obtaining the actual economic production quantity. The natural answer is that it is quite permissible to use this method if any time or effort can be saved. However, if one has gone so far as to obtain the index ratios required for determining the allowable variation, it would be more advisable to obtain the value for Q_u from K_F/K' in passing, and then gain the benefit from having a range of allowable variations in production quantities established, the limits for which will be E and unity. In the end this will provide an opportunity for greater control of production schedules in meeting fluctuations in the sales demand and a simplification of departmental routine that will far outweigh the value of increased accuracy.

Loss Due to an Uneconomic Production Quantity

The foregoing discussion has established the mathematical basis for the first part of the calculation sheets, and a similar basis must now be established for the second part. If a reliable index is to be developed for controlling the use of any simplified form it must be derived from some condition which represents the fundamental situation underlying a given problem. The one condition which will satisfy this situation may be found in the increase in cost over the minimum cost incurred by the production of a quantity varying to some degree from the economic quantity. This increase in cost is in reality a loss because it will reduce the normal profit expected in return from the sale of each article produced at a minimum cost. The unit loss L in such a case is equal to the difference between the ultimate unit costs U_u and U_e for an uneconomically produced quantity Q_u in the first instance and an economically produced quantity

Q_e in the second, the latter being the lowest unit cost obtainable. Hence,

$$L = U_u - U_e \quad \ldots\ldots [11]$$

In order to evaluate the loss, reference must be made to the general expression for the ultimate unit cost[8]

$$U = c' + \frac{F}{Q} + \frac{I_s}{Q} + \frac{I_w}{Q} + \frac{V}{Q} + \frac{D'}{Q} \quad \ldots\ldots [12]$$

where c' = unit production cost (as before)
F = total preparation charges
I_s = total interest charges on capital invested in inventory
I_w = total interest charges on capital invested in work in process
V = total space charge on articles in inventory
D' = total loss due to deterioration.

As this study is primarily concerned with the problem of simplification it will be permissible to omit the factors f, Δ, and θ from the expressions for the major items in the foregoing equation for reasons similar to those given in the first step, and thereupon the term D' will become zero. To avoid a repetition of the complex expression for U given in the original paper, Equation [12] can be evaluated for use in this discussion by omitting the foregoing factors and grouping the various items according to their relation to the quantity Q as follows:

$$U = \left[c' + \frac{F \cdot i}{2Y_a} \left(1 - \frac{Y_a \cdot k_p}{D} \right) \right] + \frac{F}{Q} + f' \cdot Q \quad \ldots\ldots [13]$$

where

$$f' = \frac{c' \cdot i}{2Y_a} \left(1 - \frac{Y_a \cdot k_p}{D} \right) + \left(\frac{m + c'}{2} \right) i \cdot t + \frac{v \cdot B}{Y_a} \left(1 - \frac{Y_a \cdot k_p}{D} \right) \quad \ldots\ldots [14]$$

or

$$= \left[K'_s + K'_w + K'_v \right] \cdot \frac{1}{Y_a}$$

It should be noted at this point that the item F contains all factors the total values for which depend upon the lot as a whole and are independent of the quantity, and that the term f' contains all factors the values of which are dependent upon the quantity when the lot is referred to. Now the actual expression for U_u and U_e can be obtained from the general expression for U (Equation [3]) by replacing Q by Q_u and Q_e, respectively, and when these expressions are substituted in Equation [11] and the indicated subtraction performed, the expression for the loss becomes

$$L = \left[\frac{1}{Q_u} - \frac{1}{Q_e} \right] \cdot F + [Q_u - Q_e] \cdot f' \quad \ldots\ldots [15]$$

Limits of Usefulness for Any Form

If an expression for Q_u is derived from Equation [15] in terms of the loss L and substituted in the expression for E (Equation [4]), it will be possible to obtain an expression for the limits E_l which will govern the application of any simplified form to a specific problem when the extent of this loss or the permissible increase in cost is specified. This may be accomplished by transposing the terms in Equation [15] so that

$$\frac{F}{Q_u} + Q_u \cdot f' = L + \frac{F}{Q_e} + f' \cdot Q_e$$

and by introducing the relation

$$f' = \frac{F}{Q_e^2} = \quad \ldots\ldots [16]$$

where

$$Q_e = \sqrt{\frac{F}{f'}}$$

which was obtained from Equation [2] by substituting the term f' for those items which it represents by definition (see Equation [14]), so that

$$\frac{F}{Q_u} + Q_u \cdot \frac{F}{Q_e^2} = L + \frac{F}{Q_e} + \frac{F}{Q_e}$$

Now this expression when multiplied by Q_u and equated to zero becomes

$$Q_u^2 \cdot \frac{F}{Q_e^2} - Q_u \left(L + \frac{2F}{Q_e} \right) + F = 0$$

and finally the desired expression for Q_u can be obtained by solving this quadratic equation. Accordingly

$$Q_u = \frac{(L + 2F/Q_e) \pm \sqrt{(L + 2F/Q_e)^2 - 4 \cdot F^2/Q_e^2}}{2 \cdot F/Q_e^2}$$

However, this expression can be put into a more workable form if Q_e is removed from each term (Q_e^2 from those under the radical) and placed at the beginning of the expression, so that when cleared of fractions it becomes

$$Q_u = Q_e \cdot \left[\left(\frac{L \cdot Q_e}{2F} + 1 \right) \pm \sqrt{\left(\frac{L \cdot Q_e}{2F} + 1 \right)^2 - 1} \right]$$

and then if the terms in the parentheses are replaced by the arbitrary relation

$$K_s = \left[\frac{L \cdot Q_e}{2 \cdot F} + 1 \right] \quad \ldots\ldots [17]$$

$$Q_u = Q_e \cdot [K_s \pm \sqrt{K_s^2 - 1}]$$

At this point it will be advisable to obtain the basic expression for the limits of usefulness E_l, before attempting to evaluate the expression for K_s, as that will involve setting up another relation for the loss L. Accordingly, if the expression given for Q_u is substituted in Equation [4], it will be found that Q_e cancels out and

$$E_l = K_s \pm \sqrt{K_s^2 - 1} \quad \ldots\ldots [18]$$

Naturally, as there are two roots for the expression within the radical depending upon the sign, the maximum limit E_M will be obtained by the plus (+) sign and the minimum limit E_M by the minus (—) sign. However, for the purposes of the calculation sheets only the higher or maximum limit will be used, as the value for the approximate or uneconomic quantity will be always greater than the exact or economic quantity.

Second Expression for the Loss

Until the terms represented by K_s have been replaced by terms, the values for which may be found in the data, or have been previously determined for other purposes, little practical value can be realized from the expression for E_l. As already stated, this will require another expression for the loss L which can be obtained by considering it as a function of the ultimate

[8] A full derivation of this expression will be found in the original paper. See footnote 2.

unit cost U_e and by introducing the loss factor λ, which will be explained later in detail when its utility has become more evident, so that

$$L = \lambda \cdot U_e \quad \ldots\ldots [19]$$

in which case the expression for U_e can be obtained from Equation [13] by inserting Q_e in place of Q. Moreover, for greater ease in handling the mathematics, certain other terms will be temporarily grouped by letting

$$K_u = \left[c' + \frac{F \cdot i}{2 \cdot Y_a} \cdot \left(1 - \frac{Y_a \cdot k_p}{D} \right) \right]$$

whereupon

$$U_e = \left(K_u + \frac{F}{Q_e} + Q_e \cdot f' \right)$$

or if the relation in Equation [16] is used again to eliminate the term f'

$$U_e = K_u + 2 \frac{F}{Q_e} \quad \ldots\ldots [20]$$

Accordingly, the second expression [19] for the loss can be rewritten as

$$L = \lambda \cdot \left(K_u + 2 \frac{F}{Q_e} \right)$$

and if this is substituted in Equation [17], an expression is obtained where

$$K_e = 1 + \lambda \left(\frac{Q_e}{2} \cdot \frac{K_u}{F} + 1 \right) \quad \ldots\ldots [21]$$

Problem Index

On the other hand, if the value for the loss L as given in Equation [19] had been directly substituted in the expression for K_e (Equation [17]) before the expression for the minimum ultimate unit cost U_e was inserted, it would have been found that

$$K_e = \lambda \cdot U_e \cdot \left(\frac{Q_e}{2F} \right) + 1$$

or

$$= 1 + \lambda \cdot \left[\frac{U_e Q_e}{2F} \right] \quad \ldots\ldots [22]$$

Herein lies a very interesting fact which is well worth a moment's digression in order to investigate its identity. If the symbol K_o is allowed to represent those terms which have been placed within the parentheses in Equation [22], so that

$$K_o = \frac{1}{2} \left[\frac{U_e \cdot Q_e}{F} \right] \quad \ldots\ldots [23]$$

K_o can then be defined as the ratio of the total cost $U_e \cdot Q_e$ of manufacturing a lot of an economic size, all contributary charges being included, to the total cost F of preparing for the manufacture of the lot. As the fundamental situation underlying any problem of economic production quantities is based upon the relative proportion of these two major cost items, K_o will henceforth be designated as the "problem index," and its numerical value may be used with certainty as one of the controlling factors in the determination of the limits of usefulness.

Evaluation of K_o

Accordingly, if the expression for U_e from Equation [20] be substituted into that for K_o (Equation [23])

$$K_o = \frac{Q_e}{2F} \left(K_u + \frac{2F}{Q_e} \right)$$

or

$$= 1 + \frac{1}{2} \cdot \frac{Q_e K_u}{F} \quad \ldots\ldots [24]$$

which, when the full expression for K_u is reintroduced, becomes

$$K_o = 1 + \frac{Q_e}{2} \cdot \left[\frac{c'}{F} + \frac{i}{2Y_a} \cdot \left(1 - \frac{Y_a \cdot k_p}{D} \right) \right] \quad \ldots\ldots [25]$$

This, of course, is the fundamental expression for K_o, but experience has demonstrated that the ultimate value of the parenthesis represented by K_u/F depends almost entirely upon the ratio c'/F, and for the purposes of the calculation sheet the terms

$$i/2Y_a \left(1 - \frac{Y_a \cdot k_p}{D} \right)$$

may be disregarded in computing the values of K_e or K_o. This can be easily demonstrated by the fact that if any one of the values for both Y_a and D most commonly encountered in such problems be introduced, the value of the parenthesis, where k_p will never be greater than unity, will evidently be almost equal to one, and when it is multiplied by the daily unit interest charge, the value of which is not often greater than 0.000666, and then divided by twice the average daily rate of consumption, the final total value for this group of terms will undoubtedly be too small to have any material influence upon the results. On this basis, then

$$K_o = 1 + \frac{Q_e}{2} \cdot \frac{c'}{F} \quad \ldots\ldots [26]$$

Should it happen that the economic production quantity Q_e had been determined in any case, prior to the use of the method proposed herein, and that it is now desirable to establish an economic range for production quantities, instead of having one inflexible quantity, either of the Equations [25] or [26] may be used as they stand. However, if a production quantity Q_u is to be calculated from some simplified form and K_o has not been previously determined, it will be necessary to eliminate Q_e from this expression. This can be accomplished by introducing the short-cut method, previously described, whereby Q_e will be replaced by items the values for which are readily available from the calculation sheets. Hence, from Equation [10], if

$$Q_e = \sqrt{\frac{R_w}{R_c} \cdot \frac{2 \cdot F}{(m + c')} \cdot \frac{1}{i \cdot t}}$$

Equation [26] becomes

$$K_o = 1 + \sqrt{\frac{R_w}{R_c} \cdot \frac{c'}{F} \cdot \frac{1}{2 \cdot i \cdot t \cdot \left(1 + \frac{m}{c'} \right)}}$$

and this expression has been used as the basis for the procedure given in Part II of the calculation sheets.

Factors Controlling the Limits of Usefulness

When the expression for K_o from Equation [24] is introduced into that for K_e (Equation [21]) in place of those terms in the parenthesis which it represents, it will be evident that

$$K_e = 1 + \lambda \cdot K_o$$

and that the limits E_l for the range of usefulness governing any simplified form will depend only upon the problem index and

the loss factor. This factor can now be defined as the proportional amount by which the ultimate unit cost U_u for an uneconomic quantity exceeds the minimum or ultimate unit cost U_e for an economic quantity. This statement may be illustrated graphically by the diagram given in Fig. 1 or mathematically by the expression

$$U_u = U_e + \lambda \cdot U_e$$

or

$$= U_e(1 + \lambda)$$

Actually, when a specific production problem is under consideration, as designated by the particular value for K_o, it will be found that this loss factor λ will be the one which controls the final choice of the limits of usefulness, because it is a measure of the extent to which the profit normally expected in return from the sale of an article when manufactured in an economic quantity will be reduced should an uneconomic quantity have been produced instead.

How the Loss Factor May Be Employed

Ideally, any production executive desires to manufacture the products of his company at the lowest attainable unit cost; this naturally will be the minimum ultimate unit cost U_e obtained only for an economic quantity, where $\lambda = 0$. In how many cases does this situation actually exist in industry? This may be answered for any specific case if the true economic production quantity is determined from Equation [2] and compared with the quantity which is now being used in production for each manufacturing lot. Many of these executives will be surprised at the divergence which exists in current practice from the ideal conditions. This situation can be arbitrarily improved, if not entirely corrected, by the use of the right-hand portion of the chart described in the next section and included with the calculation sheets in Table 4. If the actual quantity Q_a produced in each lot is introduced into Equation [4] in place of Q_u, the amount E_a by which it varies from the economic quantity Q_e can be easily determined because

$$E_a = \frac{Q_a}{Q_e} .$$

Then the loss factor λ_a which indicates the increase in cost for the quantity Q_a can be found by reading off the value of the curve nearest to the point of intersection of a horizontal line drawn through the appropriate value of K_o with a vertical line drawn from E_a. If greater accuracy is desired, interpolation between curves is permissible. The value thus obtained for λ_a can be used as a measure to guide the decision of executives in determining to what degree it can be reduced if it is not feasible at the moment to make it zero by the adoption of economic quantities for production purposes. Should some smaller value λ_d be decided upon, the procedure outlined may be reversed in order to obtain the value for the desired production quantity Q_d. In most cases it will be inadvisable to select too small a value for λ_d as no advantage can then be had from the use of either simplified forms or a range of production quantities.

In the first case, if a reasonable value for λ_d which will show a substantial increase in profits is selected, normal fluctuations in the rate of consumption and other errors arising from uncontrollable circumstances in production as well as the need for too frequent recalculation of the production quantities may be easily avoided, thereby simplifying departmental routine. It is impossible to predict in advance the most desirable value for λ_d without a detailed study of each case, as in most it depends upon the conditions peculiar to each type of industry or to the individual concern. Once this preliminary work has been accomplished for a number of typical cases and an appropriate value has been selected, no further recourse need be made to Equation [2] for the value of the true economic production quantity Q_e as the simplified forms will yield entirely reliable values.

Graphical Means of Solution

Now that means have been devised for determining the controlling factors λ and K_o for the limits E_l of the range of usefulness, some rapid method of solution must be provided which will not involve any of the implied calculations in order to obtain a limit for production quantities beyond which the resulting

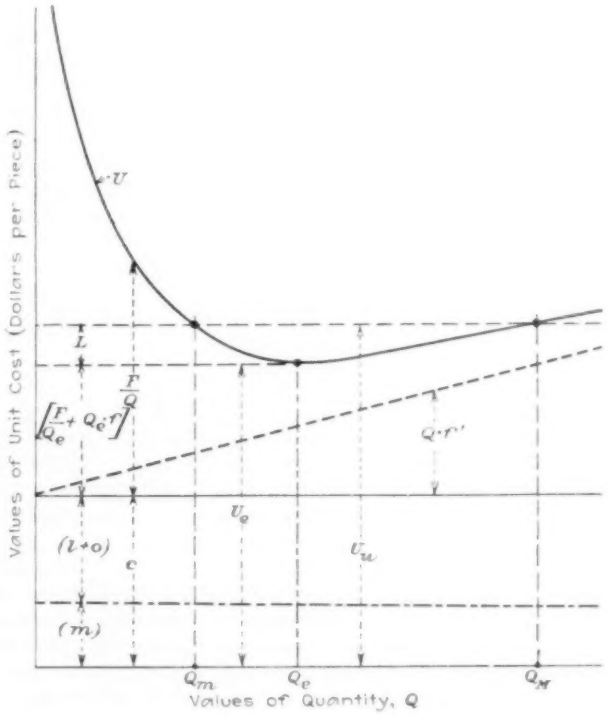


Fig. 1 Ultimate Unit Cost Curve U

increase in cost makes it inadvisable to go. This will be the maximum permissible variation E_M in the answer which can be obtained from the expression for E_l by using the positive (+) sign in Equation [18]. This equation when expressed in terms of these two factors just described becomes

$$E_M = K_e + \sqrt{K^2_e - 1}$$

$$K_e = (1 + \lambda \cdot K_o) \quad \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

The simplicity of the expressions in Equation [27] immediately suggests a graphical form of solution (see Table 4), which was accomplished by plotting the values of K_e as ordinates and the values of E_M as abscissa, and drawing a series of curves each representing a definite value for λ. Such a chart is universal in its application; however, if the desired limiting value for λ_d can be selected by executive policy in advance, a similar chart can be prepared for use in a given plant, and then only the curve based on this value need be plotted, thereby relieving the subordinates in the production department of any responsibility in the choice of a correct value.

Applications of the Maximum Limit of Usefulness

Either of these charts for the maximum variation in the answer E_M can be used as described in a preceding section for

the determination of the value of λ_d in addition to completing the procedure outlined in the calculation sheets for determining the limiting value e_M for the form index e for any problem. In this latter case E_M must be transformed into e_M by use of Equation [6], where

$$e_M = \frac{1}{E_M^2}$$

but to avoid the necessary calculations the corresponding values for E_M and e_M have been plotted together on the bottom scale of the chart in Table 4 over the range that

$$E = E_M > 1.$$

The appropriate value for e_M can then be read off directly and compared with the values for e_a ($= {}^2/_3$) to check the accuracy of the method in Part I or used in Equation [8] to obtain a value for R which will represent the smallest value for any index ratio that may be justifiably used in selecting a simplified form to suit a specific case. In addition to this, E_M may be used to provide the upper limit Q_M for an allowable range of variation in production quantities which will permit greater latitude in the control of schedules and an adjustment for ordinary fluctuations in the sales demand, where

$$Q_M = Q_c \cdot E_M$$

or

$$= \frac{Q_a \cdot E_M}{E_a}$$

Minimum Limit of Usefulness

If such a provision will be of advantage, a still greater one can be realized if a lower limit or minimum allowable variation in the answer E_M is available. This may be determined from a similar chart prepared from the expression

$$E_m = K_e - \sqrt{K_e^2 - 1} \quad \ldots\ldots\ldots\ldots [28]$$

where K_e and naturally K_o would be the same as given for Equation [27] but where the minus (—) sign is used instead. However, it should be remembered that this minimum limit has no significance in connection with the selection of simplified forms, as all uneconomic quantities so derived will be greater than the economic quantity.

Conservation of Capital and the Limits of Economic Production

If a production quantity Q_M greater than the economic quantity is permissible, a smaller quantity Q_m for which the loss factor λ_l is the same is even more so as the allowable range of variation can be increased to include all quantities lying between for which the respective values of λ will be less than that for λ_l. Of greater importance, however, is the fact that the production of the smaller quantity Q_m will require less working capital than any other larger one, and the capital thus saved may be advantageously diverted to other gainful purposes. If capital can thus be conserved without impairing the expected profit to any greater degree, the quantity Q_m can be determined from the chart given in the calculation sheets Table 4 where the curves from Equations [27] and [28] have been combined.

The procedure in this case is quite simple, as the value for λ_d can be determined in the same manner as described, from the right-hand portion of the chart (Table 4). Then if the horizontal line through the appropriate value for K_e is followed over into the left-hand portion of the chart until it intersects with a curve having the same value for λ_d, the value for E_m will be found directly below this point on the scale at the bottom. Finally, if the values of E_M and E_m are read off and substituted in the expression

$$Q_m = Q_M \cdot \frac{E_m}{E_M} = Q_e \cdot E_m$$

where Q_M was determined from E_m in the right-hand portion of the chart, the value for the quantity which will conserve the greatest amount of capital will be obtained. Accordingly the limits of variation in production quantities will be Q_M and Q_m.

Determination of Savings

Another advantage can be gained from the use of the combined charts for E_M and E_m (Table 4) through the method it provides for determining the savings arising from any improvement in manufacturing operations. This will be of much assistance to production executives as it introduces a new tool for management to measure its proficiency and to aid them in their selection of the best methods. The savings which can be achieved from the production of the best quantity in any lot, the nature of the process being unchanged, may be determined by comparing the loss factor λ_a for the quantity currently used for production Q_a with the value of λ_d for the desired or proposed production quantity Q_d as obtained by the procedure outlined for a given product, the index for which is a specific value of K_e. In this case if the actual gain or savings G in dollars is measured by the factor g when

$$g = \lambda_a - \lambda_d \quad \ldots\ldots\ldots\ldots [29]$$

then

$$G = g \cdot U_a \quad \ldots\ldots\ldots\ldots [30]$$

On the other hand, if the method of manufacture of any product is improved at the same time, the value of K_e for the new process K_n will be different from that for the old K_a. In this case λ_a must be determined for values of $K_e = K_a$ and Q_a, and then if the horizontal line from the value of $K_e = K_n$ is followed as desired either to the right or left until it intersects the vertical line from Q_d, which will now represent the desired production quantity for the new process, the value for λ_d will be that assigned to the curve which passes through this point of intersection, whereupon the values of g and G can be obtained again from Equations [29] and [30]. It should be noted that the value of g with regard to sign is not affected by the fact that the value for λ_d was obtained from either the right-hand or left-hand portion of the chart.

Final Treatment of a Simplified Form

The fourth and final step toward simplification may be accomplished in two ways; first, by studying the arrangement of terms resulting from the substitution of the actual expressions for the major elements in the particular simplified form selected; and second, by expressing certain of these terms as constants, depending upon the industry and type of process. The first is entirely optional with the person making the calculations, but it will be found that a regrouping of the various items will reduce the final labor of calculation after the appropriate numerical values have been introduced and that, in certain cases, items which appear both in the numerator and denominator will cancel out or become combined. The second may be achieved by the proper selection of values for such terms as i, k, n or k_p, and r. Any one at all familiar with the handling of mathematical expressions would naturally perform these steps before attempting to compute the answer; however, this suggestion at least will not be amiss as it will serve to remind those interested that such treatment will always be of assistance.

Future Developments

The final form for the calculation sheets appearing in Tables 1, 2, 3, and 4 was adopted, as it is believed that the methods

developed by means of this study could be more readily applied in this manner to the practical problems of industry and that continued recourse to the theory could thereby be avoided. Of course it would be possible to devise other forms of presentation and a wholly graphical method would be quite practicable. It is hoped, as experience grows in the use of simplified forms, that numerical values can be assigned to the various index ratios which will definitely indicate the range of usefulness of each form, as it would be possible under such conditions to omit the procedure outlined in Parts I and II. Likewise, a further study of the values of the factors E_m, E_a, e_a, and λ will materially aid in the universal acceptance of these methods. In order to illustrate the application of the proposed methods, a sample calculation for a specific problem is given, Table 6. By reference to Tables 1 and 6 the identity of each numerical value used can be easily ascertained.

TABLE 6

(Data Obtained from a Paper Box Manufacturer for the Selection of Suitable Simplified Forms of the Economic Production Quantity Formula)

Items	Symbols	Units	Data
Unit production cost	c'	\$/pc.	0.0683
Unit material cost	m	\$/pc.	0.0521
Total set-up cost	M	\$	6.50
Total cost of issuing order	O	\$	0.48
Total preparation cost = $(M + O)$	F	\$	6.98
Unit production time	t	day/pc.	0.00025
Consumption rate	Y_a	pc./day	67
Interest rate per day	i	%/day × 1/100	0.000666
Space charge per day	v	\$/cu. ft./day	0.0001145
Unit of space occupied by article	B	cu. ft./pc.	0.909
Height provided for storage	h	ft.	10.0
Number of batches	n	....	1/0 = ∞
Process factor	k_p	....	1
Rate of deliveries to stores	D	pc./day	4000

In applying the data given in Table 4, reference should be made to the procedure outlined in the calculation sheets (Tables 1 to 4).

PART I — SELECTION OF FORM

Item 1 $\dfrac{0.0001145}{0.000666} \times \dfrac{2}{10} = 0.0344$

Item 2 $\dfrac{0.909}{0.0683} = 1.33$

Item 3 $0.0344 \times 1.33 = 0.456 = R_v$

Item 4 $\dfrac{1}{67} - \dfrac{1}{4000} = 0.01465$

Item 5 $\dfrac{0.00025}{0.01465} = 0.0170$

Item 6 $\dfrac{0.0521}{0.0683} + 1 = 1.763$

Item 7 $0.0170 \times 1.763 = 0.0299 = R_w$

Item 8 (a constant) $= 1.0 = R_s$

Item 9 $0.456 + 0.0299 + 1 = 1.486 = R_c$

Item 10 $1.486 \times \dfrac{2}{3} = 0.99$ (by inspection)

Evidently the index ratio R_s is the only one the value of which is greater than $^2/_3 R_c = 0.99$

Item 11 Therefore, the appropriate simplified form will be

$$Q_s = \sqrt{\frac{F \cdot Y_a}{\frac{c' \cdot i}{2}}}$$

because the parenthesis $\left(1 - \dfrac{Y_a}{D} k_p\right)$ can be omitted from the denominator of Q_s when Y_a + item 4 $(67 \times 0.01465 = 0.981)$ is greater than 0.9.

PART II — TO CHECK FOR FORM SELECTED AND TO DETERMINE THE LIMIT OF PERMISSIBLE VARIATION

Item 12 $\dfrac{0.0299}{1.486} = 0.02012$

Item 13 $\dfrac{0.0683}{6.98} = 0.00979$

Item 14 $0.02012 \times 0.00979 = 0.000197$

Item 15 $0.000666 \times 0.00025 \times 1.763 \times 2 = 0.000000587$

Item 16 $\dfrac{0.000197}{0.000000587} = 335$

Item 17 $\sqrt{335} = 18.3$

Item 18 $18.3 + 1 = 19.3 = K_o$

Item 19 Referring to the Chart (Table 4) and selecting the curve $\lambda = 0.001$ as a reasonable allowance for an increase in cost $= 0.675 = e$

Item 20 $1.486 \times 0.675 = 1.0030 = R$

Item 21 Comparing the value of R (item 20) with the value of R_s, the index ratio for the form used, it is evident that then nature of the problem demands, if accuracy is required, the use of the form which will include with the element depending on R_s the element which depends on the next largest index ratio, R_v in this case. However, as R only exceeds R_s by 0.003, the form as originally selected should be used, because the saving in effect by its use will be greater than any saving from increased accuracy ever could be.

Digressing to calculate the quantity Q to be used as the size of the production lot from the form

$$Q_s = \sqrt{\frac{F \cdot Y_a}{\frac{c' \cdot i}{2}}}$$

$$Q = \sqrt{\frac{6.98 \times 67}{0.683 \times 0.000666 \times {}^1/_2}} = \sqrt{\frac{935.32}{0.000045533}} = \sqrt{20{,}629{,}430} = 4542$$

which will be a satisfactory production quantity. To compare this with the true economic quantity if

$$Q_e = \sqrt{\frac{R_s}{R_c}} \times Q$$

then

$$Q_e = \sqrt{\frac{1}{1.486}} \times 4542 = 0.820 \times 4542 = 3724.$$

Now returning to the calculation sheets, if from

Item 22 $E_a = 1.21$ and $E_m = 0.822$

the allowable range of quantities for purposes of production control will be

$Q_M = E_M \cdot Q_e = 4546$ for the upper limit

$Q_m = E_m \cdot Q_e = 3061$ for the lower limit

which ought to provide sufficient latitude in arranging production schedules to account for ordinary fluctuations in the sales demand.

Discussion

B. COOPER. Before deciding upon the accuracy of the formula that should be used in determining economical production quantities, it is well to make a casual survey of the precision with which the principal terms in the formula can be determined. At the first glance it might be supposed that the consumption rate is the term in the formula that could be determined with the least precision. However, there are many conflicting opinions as to the methods of arriving at the other terms in the formula. Differences in opinion exist as to whether general overhead should be added to the unit production cost for calculating economic production quantities. The question of whether overhead should be applied to the preparation cost has never been definitely settled.

Machines are often set up by foremen and sub-foremen, who charge their time to departmental overhead. Mr. Kent, in his paper, states that business return on investment should be no less than one and one-half to three times the safe return to be realized on sound, marketable securities.

The precision with which the foregoing factors can be obtained makes the application of the approximate formula $Q = \sqrt{\dfrac{FYa}{\frac{C'i}{2}}}$, referred to in Professor Raymond's paper, of sufficient accuracy except where the time to manufacture a quantity exceeds one-third of the time to consume it, in which case the error in the economical production quantity based on the approximate formula will exceed 20 per cent and increase very rapidly with the increase in the ratio of the time to produce to the time to consume. When this ratio exceeds one-third, a very simple way of correcting the quantity calculated by the approximate formula is to apply precalculated correction factors, depending on the ratio of the time to produce to the time to consume. These correction factors are often important, for when this ratio is $^3/_4$ the calculated production quantity is only 50 per cent of what it should be.

Whether to use overhead on the preparation cost or whether to use a high interest rate depends upon the circumstances at hand. If the preparation cost is relatively high and the production costs

are low, as might be the case in heading, slotting, and thread rolling machines, the overhead should not be included in order to prevent excessive inventories, in most cases. The same results can be obtained by introducing different arbitrary constants into the formula for different departments. This procedure can be justified in view of the fact that no provision can be made in the formula for deterioration and obsolescence.

The application of economical production quantities becomes a little more involved when one has to deal with a series of operations. When the first operation is performed on an automatic machine with a high set-up cost and a low production cost, and the second operation is a hand operation with a high labor cost and a low preparation cost, the resultant production quantity will be uneconomically low for the automatic machine and too high for the hand operation. In this case it may be expedient to calculate and schedule two quantities with a provision for stocking the material between the first and second operations. It is generally found expedient to stock items before expensive finishing operations are applied.

In preparing economical production quantities for punch-press work the average number of pieces that could be run on the die before grinding is necessary should be taken into account as well as the average number of times that it may be necessary to grind the die in order to produce the economical quantity. When new quantities are introduced or radically changed, the quantity should be checked by the engineering department for contemplated changes in design, by the stock keeper for space and deterioration, and by the foreman for manufacturing difficulties.

Various means are used to simplify the mathematical calculations for determining economical production quantities. The writer had devised a special nomographic slide rule for this purpose which is being used in several plants. However, more important than the means of calculation is an intelligent study and application of the principles involved. A man in charge of this work should not only understand the theory involved, but should be familiar with manufacturing problems.

Few plants are so organized that all the necessary data for calculating economical production quantities are readily available. Many plants that have well-organized cost accounting systems and good inventory records from which consumption rates can be figured lack machine set-up costs. The machines are often set up by sub-foremen or day workers. Until the cost department is ready to supply the necessary data, set-up costs, production costs, and consumption rates should be estimated in order to get the system going. It might be well to establish a quota for the number of economical production quantities that should be figured, checked, and ready for issue each week. By this means one concern placed more than 6000 items on an economical production quantity basis in less than six months.

In addition to the direct saving in machine-preparation costs and inventory-carrying charges, the application of economical production quantities brings about more efficient plant operation.

SANFORD A. MOSS.[9] There was a time, within the memory of older engineers, when machinery was designed on the basis of experience as recorded in the brain of the designer without the formulas, theory of elasticity, and mathematical knowledge of the present day. We have passed beyond this stage so far as machine design is concerned, but have not passed beyond it so far as manufacture is concerned. For this reason the maximum of simplicity is necessary in the initial stages of application of mathematics to production control. Mr. Best's paper fully satisfies this criticism, and he gives a remarkably simple presentation; nevertheless he does not seem to have made any sacrifice so far as utility is concerned.

A usual factor in an economic lot formula is the cost of preparation or set-up charge. This seems to be constant for Mr. Best's case, so that it does not appear as a variable. In order that it may be seen just how it disappears as a variable, it would be desirable if Mr. Best would give the steps in the deduction of his formula.

Professor Raymond's paper seems as complicated as Mr. Best's is simple, and it is questionable if such a degree of complication is warranted in the present state of the art. If one set a professor of theory of elasticity to making a design for a wheelbarrow, he would achieve a certain result, but a useful result could be obtained by much simpler methods. We of course desire the accuracy obtained by the use of all of the variables which Professor Raymond gives, but have the difficult problem of obtaining such accuracy by much simpler methods than those in his paper.

Mr. Kent's paper gives a very interesting introduction, but just when one looks for a means of applying the principle so well set forth in the form of formula, the paper terminates. It would be desirable if some of the formulas used by Mr. Kent could be afforded.

W. L. JONES.[10] From time immemorial authorities on the subjects of production scheduling and stock maintenance have preached rapid turnover, but have nearly always further stated that in placing orders for stock one should take into consideration such factors as storage space required, value of the article, and cost of setting up machines or placing orders. Frequently the continual drive of management and the bankers on capital turnover has caused the preparation costs to be lost sight of and ignored.

Too often the attempts of pure judgment, based only on observation, to keep a true balance between preparation costs and investment charges have failed because the one was hidden in the general labor costs and the other fully exposed to view and criticism in the financial statements.

The mustering of scientific reasoning and mathematical formulas to bring to light in a form as positive as the balance sheet the cost factors involved in ordering and the effects of incorrectly balancing those factors has done much to convince management that investment in materials of manufacture can be more than a necessary evil endured for the sake of insuring production continuity.

General adoption of the principles of economic production quantities has brought into use nearly as many formulas as there are users, formulas varying in complexity from Mr. Best's simple equation in three variables to Professor Raymond's radical embracing most of the letters of two alphabets. The tendency is as would be expected—toward simplification. The approximations in use apparently arise from two considerations—first, for ease of calculation; second, to permit the use of data readily available for computation. For rapid slide-rule calculation it is desirable to eliminate as many as possible of the additions and subtractions. For the second consideration, it is usually unwise, as Professor Raymond says, to attempt to evaluate such intangibles as an obsolescence coefficient, and under some conditions other factors are equally indeterminate. Every manufacturing problem has its own best approach; it is the problem of those entrusted with the administration of production quantities control to arrive at the formula best suited.

It is toward this necessity for the choice of one or more approximate formulas, according to the demands of the many factors involved, that Professor Raymond's paper makes a valuable con-

[9] Engineer, Mechanical Research Department, River Works, General Electric Company, West Lynn, Mass. Mem. A.S.M.E.

[10] Order Planning Department, Western Electric Company, Inc.

tribution. It is only by a complete analysis of all possible conditions of manufacture and all of the elements that are affected by lot sizes that general or specific conclusions of value to the manufacturer may be reached.

While the writer feels that many of the steps specified by Professor Raymond in his procedure for determining the allowable approximations are more complicated than many would find it profitable to follow, particularly if the product of manufacture is of great variety, still he is sure that only by a thorough understanding of all that the author has shown in detail can one be certain that the more arbitrary approximations that may have to be decided upon from day to day are well founded and safe to apply.

PAUL N. LEHOCZKY.[11] The author's formula is no doubt valuable from the mathematical and the scientific standpoint. The emphasis on saving is important; the method of illustration good.

Formulas are dangerous, however, especially when used by individuals who cannot or who do not care to investigate them. A general rule of this kind automatically creates the assumption that it will hold for any case and that the factors appearing in it are equally general. This, however, is not the case. No two plants will have the same factors present, considering factors from the weighted standpoint.

A slight shift in the determination of, let us say, the factor F will cause a serious error in the final result. This raises the problem of uniform accuracy in determining the factors. Highly accurate factors are useless when others represent mere guesses. This is especially the case if the added complication of relative importance is also considered.

This type of formula concentrates on the development of high efficiency in one certain function of manufacturing. An effort to follow the formula to the letter may lead to serious changes in the existing balance of the plant. These changes, probably negative, will not appear in the savings as expressed by the curve. It may therefore well be that an apparent saving has in reality caused a loss, not foreseen by the man who followed the dead letter of the formula. Application along lines of the method of reasoning evolved, rather than the formula, should be urged.

GORDON PENNINGTON. The author's effort to simplify the fundamental formulas for economic production quantities deserves strong commendation as a step in the right direction. However, it is going to be necessary to carry this simplification very much further than the author has carried it before manufacturing executives, generally, will make use of these formula.

Successful production men as a class are not accustomed to relying upon mathematical formulas, and they will not do so unless these are reduced to such simple terms that no risk of error or misinterpretation is involved in their use.

Simple formulas can be arrived at either empirically or mathematically. The future standing of scientific production lot control depends upon which of these methods is followed.

The empirical method has been used by Mr. C. H. Best. From his twelve years' experience he has developed, arbitrarily, a simple formula for production lots which, judging by his success with it, has proved accurate under the special set of conditions applying in his own particular case. His formula, however, and in general all formulas developed empirically are subject to the very great disadvantage that they are not applicable to the problems of other concerns nor can they safely continue to be used if the production methods upon which they are based are changed. Empirical formulas are thus dangerous because of the ever-present possibility that they will be used under conditions to which they do not apply.

To illustrate: Mr. Best found it unnecessary to make his formula depend upon the preparation cost. Evidently this factor is practically a constant for all of the products manufactured by Mr. Best's company. But if his company were to adopt new production methods which, while decreasing the direct labor cost, considerably increased the preparation cost, it is evident from common sense as well as mathematical considerations that larger batches should be processed to secure the greatest economy. If such a change in production methods should occur while Mr. Best is still setting lot quantities for his company, the writer has no doubt that he would promptly change his formula, but if in the meantime some one else has taken his place who was not as familiar with the limitations of the formula, it is very probable that the latter would not realize the need for a change, with the result that he would either materially decrease the company's profits or, realizing that something was wrong with the formula but unable to determine just what, would give up all attempts to calculate the proper batch sizes.

The danger involved in the use of empirical formulas is that they will be used by many who do not understand their limitations and they will lead to serious losses which will unjustly discredit scientific production lot calculation. Empirical short cuts to simplification cannot be too strongly discouraged.

The only safe way is to proceed by the method which Professor Raymond has used; that is to start with the fundamental factors which are common to all industries and from these to obtain formulas which are universal in their application. These can be mathematically simplified for any clearly defined set of conditions into expressions which will still be universally applicable within the limits set and can therefore be safely used by any one who understands what these limits are. The criticism of the author's paper is simply that he did not go far enough, although this method is the only one which can be safely followed.

As a matter of fact, the mathematical solution for the most economical production lot, even in its general form, is much simpler than the paper suggests. And in all cases where production lots are delivered into stores in a single batch, and where the annual sales in dollars are more than ten times the preparation cost, the general expression can be reduced to the following form:

$$L = \sqrt{\frac{2AD}{kB}}$$

where L = the economic lot quantity
A = preparation cost in dollars
D = demand in pieces per annum
B = unit cost in dollars (not including preparation cost—this will include labor, material, and burden)
k = the sum of interest, obsolescence, deterioration, and storage charges, expressed as a fraction (not per cent) per annum of the total piece cost (k will usually have a value between 0.12 and 0.36).

The foregoing formula is an approximation, but it is a mathematically sound one, and when applied within the limits given, it gives results which are as accurate as any method of cost accounting in general use and can be applied equally to the production of anything from watch parts to furniture. It may be added that, if the example given at the end of the paper is solved by means of the foregoing formula, the result, which will be 3200 pieces, will be slightly more accurate than the author's solution

[11] Department of Engineering, Ohio State University, Columbus, Ohio. Jun. A.S.M.E.

of 3724, although the difference in the final cost per piece is only one-tenth of 1 per cent in this case.

This brings up the question of when accuracy is necessary in production lot control. Obviously it would not be highly important in the case which the author has cited, where a difference of 15 per cent in the lot quantity only affects the total cost one-tenth of 1 per cent. There are other cases, however, in which the difference between a fair guess and an accurate calculation may represent the difference between red ink and extra dividends. Manufacturing executives are first of all interested in knowing when to apply scientific production lot control.

The rule is a very simple one. When the amount of the annual sales in dollars is more than a thousand times the preparation cost for one lot, a good production man's judgment is sufficiently accurate. When the amount of the annual sales in dollars is less than a thousand but more than a hundred times the preparation cost for one lot, lot quantities should be calculated approximately; that is, a mathematical solution should be made for a few typical parts, and the lot quantities for other parts may the safely be set by comparison. When the ratio referred to is below one hundred, but above ten, calculation in each case is advisable, but the formula given is sufficiently exact. When this ratio falls below ten, the general formula should be used. When the risk of deterioration or obsolescence is high, these ratios should be doubled.

The general formula, by the way, can be expressed in the form:

$$L = \sqrt{\frac{A^2}{B^2} + \frac{AD}{KB}\left(\frac{NP}{NP - D}\right)} - \frac{A}{B}$$

where N is the number of working days per year and P is the production in pieces per day, the other symbols being the same as already given. This formula is mathematically exact for all cases.

It will be evident, from the consideration of this rule, that the real field for scientific production lot control is where a large variety of products is manufactured in relatively small quantities, but with modern production machinery, which usually requires considerable set-up and planning for each lot. The manufacture of service parts is a field which particularly calls for mathematical control. Contrary to the common belief, quantity production, least of all, requires mathematical control.

Wherever accurate calculation of production lots is justified, it will usually prove just as important to calculate the reorder point. The production engineer is just as much interested in determining when to reorder as how much to order at a time, and, particularly in the case of service parts, the proper selection of reorder points is usually important, if an excessive inventory, on the one hand, or frequent emergency shop orders to supply deficiencies, on the other hand are to be avoided. (Those who are interested in this subject will find a full discussion of it in the March, 1927, issue of *Manufacturing Industries*.)

In conclusion the writer would like to point out that the really difficult and intricate part of the problem is to determine accurately for any given company the proper value for the factors, such as the preparation cost and the obsolescence and storage charges, which govern their particular problem. There is where the process of mathematical analysis is usually necessary. When this part of the work has been properly done, it is usually possible to express the results in a form even simpler than that suggested, often merely as a table which any production clerk can use with safety.

As a final suggestion, in the interest of simplification, it is recommended that all reference to a "minimum cost quantity" as distinguished from an "economic production quantity" be avoided. As the author is understood, he means by the former the proper size of a lot *if* obsolescence and deterioration are not taken into consideration, but as in practice these factors cannot be ignored, the "minimum cost quantity" is of purely academic interest, and reference to it had best be omitted.

THOMAS D. PERRY.[12] Have any standards been developed to add to the fundamental formulas a variable for single and multiple sizes, when such are feasible?

In the case of plywood, as the size or area of individual plies increase (above a certain point) the raw material increases in unit costs. At the same time the labor of preparing and laying larger pieces is not materially greater than for smaller pieces, and therefore unit costs diminish. These are seldom compensating variables, and often are important factors in determining the size of runs.

JOHN YOUNGER.[13] The author has done a splendid piece of work in calling attention to the large sums of money lost in putting improper lots through our factories. It is to be wondered, however, if he has not made his work too mathematical for the average production man. The writer is fully convinced that the use of mathematics some day will play a necessary part in the routine of production planning just as it now does in design, but until that day comes we must have our mathematics as simple as possible and also as much of it as possible.

It is also a question as to whether the mathematics should be presented in graphic form. The writer believes this is preferable.

Further, it is a mistake to search after too much accuracy, as therein lie danger and confusion. Complicated variables should be avoided as much as possible.

For the foregoing reasons, the writer prefers a simple solution such as that which follows:

Assume production capacity of P, units of product per year.
Assume a salable quantity of p.
Assume raw material cost m per piece.
Assume final product cost M per piece.
Assume interest on both at 6 per cent per annum.

Product will be produced in $\frac{\text{salable quantity, } p,}{\text{production capacity, } P}$ fraction of a year in one lot.

Interest on raw material while in process will be 6 per cent $\times \frac{p}{P} \times m$.

Interest on finished product while in storage will be 6 per cent $\frac{1}{2}\frac{P - p}{P} \times M$.

The fraction $^1/_2$ is brought in as it is expected that on the average all the product will be sold during the total period; then interest can be charged up for one-half the amount during the whole period or all the amount for one-half the period.

The total cost then becomes $(M + m)\ p$ plus $\frac{6 \text{ per cent}}{P}$ or $(mp - M\ P + M\ p)$ for one lot.

Work this out similarly for two lots, and three lots, and four, and five, and six and thus plot a curve which, it will be found, is parabolic, such as the author's, and very similar in form and position. This curve has months as the base, 12 months representing one lot per year; 6 months, two lots; 4 months, three lots; 2 months, six lots; etc. The vertical ordinate is cost. The lowest

[12] Director, Woodworking Division, Bigelow, Kent, Willard Company, Inc., Boston, Mass. Mem. A.S.M.E.

[13] Professor, Department of Industrial Engineering, Ohio State University, Columbus, Ohio. Mem. A.S.M.E.

point of the curve represents the point where the most economical lot size is reached.

The foregoing reasoning involves very simple mathematics and has the additional advantage of placing the reasoning in graphic form.

$$Mp + \frac{6 \text{ per cent}}{P}\left(pm + \frac{PM}{2} - \frac{pM}{2}\right) =$$

Authors' Closure

Mr. Raymond. All recent attempts to study management problems through the use of methods which are familiar to the engineer seem to be condemned from the start because of the extended use of mathematics as a device for expressing in concrete form certain fundamental relations which might otherwise require pages to describe. Industrial executives seem to abhor any approach to the problems of management which savors of technical details, and in most cases they resort to the statement that management in practice is too intangible for such scientific treatment. Up to the present, management has largely achieved its successes by attacking the most obvious difficulties which were certain to yield a substantial return for the effort employed and show in the company's balance sheet at the end of the year a satisfactory increase in profits.

As time progresses and more of these difficulties are overcome, an increasing amount of effort will be required to obtain the same proportionate degree of success. Even at best a stage of diminishing returns will set in unless management is provided with more precise tools, in order to continue the search for those hidden costs which must eventually be brought to light if the present rate of progress is to be maintained. If this is to be done, the practical industrial executive must be willing to accept the product of research in management and accustom himself to the newer modes of thought, even though it may have to be expressed in terms not always familiar to him.

Any study of this sort, if it is to be of general application, must present the fundamental relations which control the general problem; only after these are unquestionably established is it wise to attempt to interpret the conclusions in terms of a specific problem, because in the natural simplification, which will necessarily follow, definite assurance must be provided that any omission or permissible deviations will not introduce errors of a more serious nature.

A mathematical formula will be of considerable advantage in this respect, because it can be employed to give full expression to the basic relationships in a symbolic form so that they can be appreciated at a glance. The presence of a formula should not necessarily imply lengthy or tedious calculations, because in the initial stages of its use the ultimate gain will come from the applications of the principles involved as interpreted for a specific case, and actual values will only be required in the later stages when it becomes necessary to establish a measure or a standard of performance as a guide to those responsible for the continuance of achievement.

In any general study such as this, certain factors peculiar to some industry undoubtedly will not be properly emphasized. However, if those interested bear in mind that when the factors, whatever they may be, are classified according to total costs, unit costs, and constants, the first two of which are the major components of the numerator and denominator, respectively, of any formula for the economic size of a production lot, little confusion will be encountered in the solution of the problem. Naturally, if the utility of any such scheme of control is to be eventually "sold" to the highest executives of the company, it must be first reduced to its simplest proportions. This can be done only by those who are thoroughly familiar with the practical side of the problem, and by reducing it to a routine form through the use of special tables, charts, or slide rules.

Mr. Pennington has added much by his proposal for selected ranges, according to the relation of the preparation cost to the cost of goods sold, for designating the degree of accuracy required in selecting an appropriate expression for determining the best lot size. His remarks illustrate admirably the conclusions which can be drawn from a practical application of Table 4 accompanying the calculation sheet.

Mr. Jones has raised in his discussion a very interesting point with regard to joint economic production quantities; that is, the situation where a fabricated part is composed of elements the manufacture of which, for convenience, cannot be considered separately. In this case, the preponderance of evidence still shows, as a result of recent study, that in all probability each element should be produced in quantities that are determined distinctly for itself and not for all combined. The deciding factor in such a situation will always be the one which will yield the lowest minimum cost for the type of processes employed. Analogous to this is the case of single or multiple sizes or strips processed at the same time. Here, too, the best lot size will be obtained for the lowest cost process.

In manufacturing to order and not to stock, economic production quantities cannot be directly applied, because the chief factor in the economic balance, in opposition to the preparation cost, is lacking; that is, the cost of capital invested in inventories, because in the first case goods are produced only as the customer requires them.

However, it will be advantageous to analyze the manufacturing problem on the basis of economic quantities and determine whether it would be wiser to obtain a year's contract, even at a lower price, than to incur the otherwise high cost of preparation. Rush orders, similarly, have no relation to economic lots as they are distinctly an expedient to remedy some emergency. Nevertheless, the situation can be improved if the machine load budget is constructed on the basis of economic quantities, as then these rush orders can be more easily processed without incurring too serious an interruption in the prearranged manufacturing schedules.

In answer to several questions raised, in connection with the deviation of the empirical formula presented by Mr. Best, it may be said that its fundamental form is similar to the one for the general formula the author has proposed, except that the elements for work in process and storage space have been eliminated. Mr. Best has not omitted the preparation charge, but owing to the fact that he has derived special formulas for substantially each individual product, of which this is one, the preparation charge has been evaluated along with all other items which could be assigned constant values and appears in the coefficient outside the radical.

Depreciation and obsolescence are two other factors which may have at times an important relation to the economic lot size. The former can be accounted for as a loss directly attributable to the ultimate unit cost, whereas the latter, owing to the uncertainties which control its occurrence, must be treated in an entirely different manner. The effect of obsolescence is to make worthless the amount of capital which has been invested in articles that become unsalable owing to a shift in the sales demand. To protect such capital, obsolescence must be provided for by the production of a lot which requires the least investment to attain a reasonably low manufacturing cost, because there the smallest amount of capital will be endangered at any one time. This raises a very important question as to whether production at minimum cost is the most economical.

Further research has proved that the economic quantity is not the minimum cost quantity and can be a very much smaller one

without impairing the gross profit which would otherwise have been earned if production had been based on the lot size for minimum cost. To demonstrate this would require the preparation of another long paper, but for the moment it is well to bear this fact in mind, as it shows conclusively the value of research methods applied to management. It is problematical in the majority of cases whether the ordinary executive, who is occupied with the details of a particular business, would have the time available to devote to the discovery of this fact by himself unless there had been some extraordinary incentive, because such men have quite enough to do without stopping to question supposedly well-established principles as apparently basic as production at minimum cost.

MR. BEST. In his discussion, Mr. Sanford A. Moss suggests that it would be desirable if the steps in the deduction of the formula were presented.

There are fifteen production departments in the plant of Eli Lilly and Company, and each department produces a line of merchandise by processes practically unrelated to the processes employed in the other departments. Instead of developing a general formula for economic production quantities, it seemed expedient to develop individual formulas for the different departments. Variations in procedure within a department would make necessary one formula for each classification of processing in that department. There are 64 formulas in use in this office, each one being applicable to only a portion of the products that are made.

Equipment "set-up" or "make-ready" costs are not factors of importance in our costs. However, for lot-size determination there are similar costs that must be considered. Standardization, assays, chemical analyses, and tests upon animals form similar costs that remain the same per lot regardless of the lot size. Planning office supervision, perpetual inventory recording, and an expensive reweighing and checking system in the raw material supply department form three other elements of cost that are constant per lot regardless of lot size. Each of these costs is expressed algebraically.

All the foregoing costs are carefully determined for each of 64 classifications of product, but in the simplified formula given in the paper all these items appear in the constants. The only variation in the formulas for the 64 classifications are variations in constants.

The variable costs that enter each formula are actual processing costs, cost of actual storage space occupied, and interest, taxes and insurance on the investment. These variable unit costs are carefully determined and expressed algebraically.

Now the first derivative of the algebraic sum of all these components of the unit cost is set equal to zero to arrive at the formula for determination of the economic production quantity.

A nomographic slide rule for each of the 64 formulas makes the job of the clerk who determines lot sizes a very simple matter. The clerk needs to know only:

1 Unit material cost
2 Number of units sold per year
3 Classification.

Answers to items 1 and 2 are always at hand when a production order is being issued. The name of the article that is to be processed and the blue-printed working formula identify the classification (item 3) very positively.

Now the selection of the proper lot-size formula is solely dependent upon classification of the product. It is not necessary to make any adjustments in any formula.

For instance, a production order is to be issued for a coated tablet that is scheduled for a triple rotary compression machine. The proper nomographic slide rule to use is headed "Compressed coated tablet—triple rotary." A straightedge is placed upon the chart, and the proper lot size is read direct. The clerk does not need to know that there is a formula. He does not need to know how to extract the square root.

The extreme simplicity of the routine operation of this system of lot size control is of course the chief virtue of the system. The local problems have been solved in a satisfactory manner. The system has accomplished rather outstanding results. These are the merits.

On the other hand, considerable time was required to originally set up the framework of the system, and considerable time is required to incorporate changes in procedure into the formulas.

This method of attack might suit some cases and be entirely unsuited to others.

MAN-52-3

Aeronautical and Automotive Service Mechanics

By A. D. ALTHOUSE,[1] DETROIT, MICH.

This paper describes the training courses for airplane and automobile mechanics as taught at the Cass Technical High School, Detroit, Mich. They have more than doubled the minimum training requirements for airplane mechanics as set forth by the United States Department of Commerce. The course for airplane-engine mechanics includes specifications of various types and gives shop work in tuning, adjusting, and overhauling engines. The course gives skill in the use of various hand tools and also teaches technical details. Automotive training includes machine fitting, internal-combustion engines, chassis details, automotive electricity, welding and engine testing.

THERE are certain fundamental things to be considered in any mechanic's training. These things and their bearing upon modern trade training may well be studied by comparing the trade-training methods in use before the World War and the methods in use today. Before the war many youngsters were taken into the mechanical industries as apprentices. The ages of these apprentices varied from 14 years up to 18 or 20 and the school grades from the sixth to the tenth. These boys worked in the shop under a competent mechanic who taught the youngsters the use of tools and the processes with which they should be familiar. Such subjects as mathematics, drawing, and science were given in regularly organized classes. These subjects were made practical, and the problems were applied directly to the work done in the shop.

The war and certain labor legislation upset this apprentice organization in Detroit almost entirely. High wages paid for work that could be learned very easily made the youngsters less eager to enter apprenticeship training. Compulsory school laws have made it necessary for the youngsters to attend school until 17 years of age or until they have completed the tenth grade. Boys leaving school at this age are not so satisfied with the wages usually paid apprenticeship boys, and they seek production work or some employment that will be more immediately remunerative.

The Michigan labor laws also have had a decided effect upon the apprenticeship systems. Due to a peculiar wording of the employers' liability act prior to 1927, employers of children under 18 years of age were put to a great disadvantage in the event of any accident occurring to young employees. The act contributed to the breaking down of the old apprentice system. During the last two years, however, some modifications have been made in the law, making it easier for employers to hire children under 18 years.

As a result of these school and labor laws, more of the burden of training for the industries has been thrown upon the public schools, and particularly upon the technical, trade, and vocational schools.

The technical school in Detroit began giving trade training in the evening classes. Whenever sufficient demand warranted the action, a day class would be started in that subject. This action soon brought to the front the type of training that might best be given to the youngsters in the day-school classes. In a large measure the evening schools have shown the way for the day-school work. Before beginning any new day-school course it is usually tried out in the evening-school classes.

Training of Aeronautical Mechanics

Due to the activities of the Department of Commerce, Aeronautics Branch, the objectives of this type of training are very well defined. The Department of Commerce issues three distinct types of licenses for pilots and mechanics, and the requirements for licensing each are very definite. These licenses are for pilots, airplane mechanics, and airplane-engine mechanics. The Aeronautics Branch of the U. S. Department of Commerce has prepared a booklet of "Air Commerce Regulations" (Aeronautics Bulletin No. 7) in which are set forth the exact requirements of training for any of the Department of Commerce licenses.

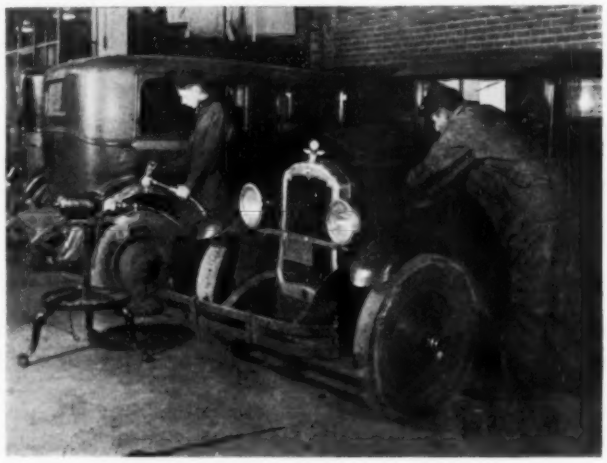

Fig. 1 Shop in Wilbur Wright Cooperative School, Detroit (This illustration shows the boys at work on automobile repair jobs. This shop is equipped to do all kinds of automobile service work.)

For a pilot's license the specified subjects are airplanes, aircraft engines, meteorology, navigation, parachutes, air-commerce regulations, and instruments.

In Detroit definite unit courses covering each of these subjects have been established in the evening schools. The public schools do not give flight training, but do give all the necessary subjects to pass the theoretical part of the Department of Commerce examination for all grades of pilots' license.

For the licensing of airplane mechanics certain training in specified subjects is demanded. However, the minimum requirements set forth by the Department of Commerce are not nearly sufficient. The prospective airplane mechanic must first be a

[1] Cass Technical High School.

Contributed by the Committee on Education and Training for the Industry and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 15, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

mechanic; that is, an accurate, conscientious, and reliable workman who takes pride in doing a piece of work well.

In order to train such a mechanic it is necessary that he do all of the usual airplane jobs several times under competent supervision and instruction, and not that he merely be told how to do them. A first-class airplane mechanic should have the following qualifications:

He should be a competent acetylene welder on tubing and thin sheet metal. He should be a better than fair woodworker, and he should be an expert wireworker on both solid wire and stranded cable. He should have some ability as a draftsman and be able to read blueprints. He should have had considerable practice in rigging flying ships, and he should have a fair understanding of the essentials of metallurgy as it concerns the metals with which he works.

To illustrate why this training is essential, take for example the repairing of a steel-tube fuselage that has been injured so

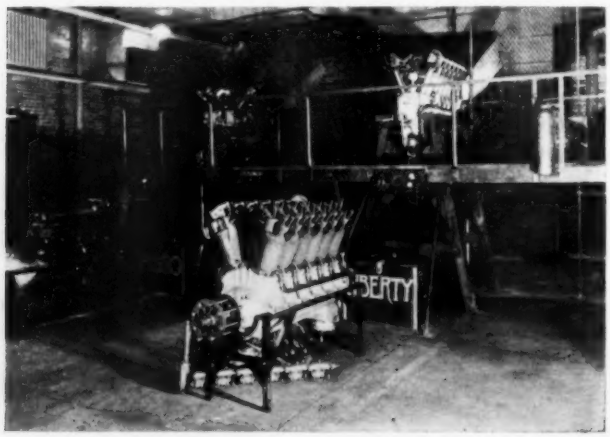

FIG. 2 AIRPLANE-ENGINE LABORATORY IN CASS TECHNICAL HIGH SCHOOL

(The running engine on a small balcony is supplied with water, gasoline, and oil from pipes under the balcony. The instrument panel contains the controls and the usual engine instruments. A duplicate engine used for assembly practice is shown in the foreground.)

that a section needs repairing. The owner must submit to the Department of Commerce in Washington a drawing or blueprint of the repairs that he proposes to make, together with complete specification of the sizes, length, and alloys of the material that he purposes to use. The engineering staff of the Department of Commerce examines these plans and specifications, and carefully checks them; and if they are approved, a set of the plans are returned to the owner, with corrections if necessary, and a duplicate set is sent to the Department of Commerce inspector for that area. The owner is then authorized to have his mechanics make the repairs, and when they are completed, the inspector determines if the repairs have been made according to the specifications furnished. It is evident that a mechanic properly prepared to do this job needs a very broad training.

In the Detroit system, the training of airplane mechanics is given in two courses in airplane construction and two courses in acetylene welding. The welding courses include some metallurgy. A special course of mathematics relating to aeronautics parallels the airplane-construction work for the student who needs more training in mathematics.

The Detroit courses have more than doubled the minimum training requirements as set forth by the Department of Commerce for airplane mechanics. This is done to more nearly fit the student for airplane work.

The training for the airplane-engine mechanic is similar. The student must be familiar with engine specifications and have had a great amount of experience in tuning, adjusting, and overhauling aircraft engines.

The courses for airplane-engine mechanics in the Detroit evening classes divide the engine work into three parts. A preliminary course in engine principles is offered first. This course gives the student experience in dismantling and assembling modern aircraft engines and gives training on the fits and clearances allowed in aircraft engines as well as instruction on timing and firing order.

The second course deals entirely with electrical work, such as ignition, starting, and lighting. A large portion of time is spent on high-tension magnetos.

The final engine course is engine testing, which is done entirely on running engines. For this subject five popular aircraft engines are mounted on stands, with propellers and guards, complete in every detail. Running adjustments are made on valves, ignition systems, and carburetors, as well as on valve and ignition timing. Some dynamometer work is done in order to teach the measurements of horsepower, torque, brake mean effective pressure, and other factors of engine performance. The aim of this part of the work is not to develop research ability, but merely to work with engines under load, and to develop the students' ability to detect and repair minor faults that will appear only under full-load operation.

In many ways the engine courses are the most satisfactory ones offered because the men are able to obtain exactly the information they need for employment in the industry as airplane-engine

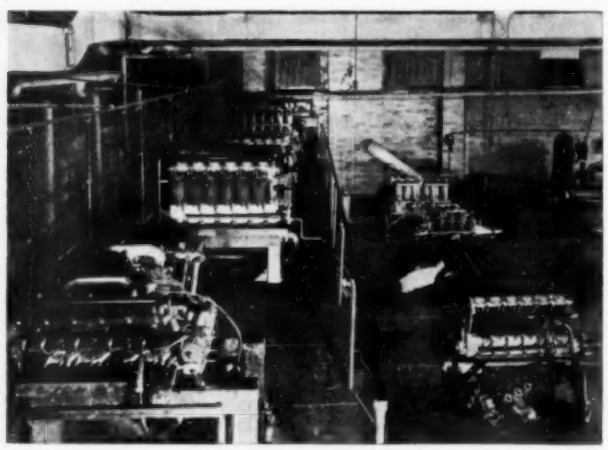

FIG. 3 SECTION OF AIRPLANE-ENGINE TESTING LABORATORY IN CASS TECHNICAL HIGH SCHOOL

(The running aircraft engines are mounted on a stand, with a guard between the propeller and the engine. These engines are used for running adjustments and timing.)

mechanics. A great number of men now employed in aircraft-engine work, but who have not as yet obtained the aircraft-engine mechanic's license, join the classes in order to get the information necessary to pass the theoretical part of the Department of Commerce examination.

Undoubtedly the public schools can be of great assistance to the aero industry in training men for aeronautical service, and this training may best be given by unit courses covering some specific work for which the particular community manifests a need.

Before aeronautical classes were offered in the Detroit public schools, a conference was held with the leaders in the aeronautical industry of the Detroit area, and the work offered was with their cooperation and sanction.

It might be mentioned for the benefit of public-school systems contemplating the establishment of aeronautical courses that both the Daniel Guggenheim Committee on elementary and secondary aeronautical education and the Aeronautical Chamber of Commerce of America are planning to furnish information gathered from the aeronautical industries that should be of value in establishing public-school aeronautical courses.

Training of Automotive Mechanics

Automotive training in the City of Detroit is given in two types of schools, technical and trade schools. In the technical school the work is divided into six divisions, each division being a distinct unit. These units are: (1) Machine fitting, (2) internal-combustion engines and chassis, (3) automotive electricity, (4) welding, (5) automobile repair, and (6) engine testing.

Machine fitting consists of hand-tool work almost entirely. The object of the course is to give skill in the use of such tools as hammers, chisels, files, taps, dies, reamers, drills, micrometers, scrapers, and other hand tools. Internal-combustion-engine work consists of engine theory and study of internal-combustion-engine construction for all types of automotive engines.

Automotive electricity consists of a technical study of direct-current electricity, induction, capacity, resistance, electrical circuits, and magnetism. A thorough study is made of the general circuits on popular automotive vehicles, with a small amount of practical experience in operating and testing these units. The evening-school course is attended largely by auto mechanics who wish a more technical training concerning automotive electrical systems.

The welding work consists of acetylene and arc welding of steel and some practice on aluminum and cast iron and brazing. The demand for welding training far exceeds the capacity of the school welding shops. This is largely due to the increasing demand for welders in all phases of production and service work.

Automobile repair consists of automobile service work on popular cars that are taken into the school shops for repairs. The time spent in this course does not permit of a very thorough training in service work, but stresses fundamentals of service operations and trouble shooting.

Engine testing consists of simple engine tests to determine the horsepower, torque, brake mean effective pressure, and thermal efficiency of popular automobile engines. The purpose of the course is to familiarize the student with the characteristic tests for engines and to recognize typical engine performance. Naturally the student learns a great deal of the finer adjustments of engines and carburetors because it is necessary that everything function well if good results appear on the curve sheets.

The standard procedure for engine testing of the Society of Automotive Engineers is followed throughout this course. All of the foregoing courses are duplicated in both the day- and evening-school classes.

The technical high-school boys study in addition to the automotive courses the following: Five semesters of English, five semesters of mathematics, two semesters of history, two semesters of chemistry, two semesters of physics, two semesters of metallurgy, and five semesters of mechanical drawing. This training is not specifically for service mechanics, but many of the graduates enter service work as well as experimental work and other jobs requiring a technical training.

The automobile service course given in the trade school in Detroit is on the cooperative basis. The boys are placed as apprentices in service stations and spend two weeks in the shop and two weeks in school. The school training consists of garage practice, technology, service management, mechanical drawing, mathematics, and English. Garage practice consists of service work on popular cars, including complete overhauls of all major units and refinishing.

Technology consists of fundamental theory of engines, electrical systems, carburetors, fuel systems, chassis units, history of the development of the automobile, and an analysis of personal attributes for successful auto-service work.

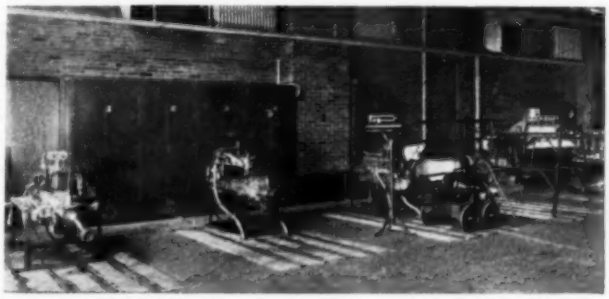

Fig. 4 Section of Automobile-Engine Testing Laboratory in Cass Technical High School

(The dynamometer and the engine-bed arrangement with underground exhaust system, are shown.)

Service management considers the problems of organization of the successful service station and studies the problems of equipment, records, overhead, personnel, and costs.

Mechanical drawing considers the usual assembly and detail drawings necessary for a complete understanding of and ability to read machine drawings. Mathematics deals entirely with shop problems and begins with fractions, decimals, and measurement.

English work in this school is almost entirely spoken, and the aim is to develop in the boy the ability to meet people and express himself clearly concerning shop matters. The Detroit public-school system maintains a placement bureau through which the industries are able to make contact with the individuals who have received the training that their work demands.

To sum up the training for automotive and aeronautical service work offered in the Detroit public schools, it may be said that the policy is to offer any courses for which there is a reasonable demand and to cooperate with the employing industries in every possible way.

MAN-52-4

Suggestions for Encouraging Education and Training for Industry

By HAROLD S. FALK,[1] MILWAUKEE, WIS.

Training of artisans and mechanics for American industry has been very much neglected in past years, and the movement for the revival of apprenticeship and industrial training can justly expect support. One of the great problems of apprenticeship and industrial training is to give the movement greater publicity, and to bring the subject before manufacturers and business men.

Local branches of the Society can effectively promote the movement by holding contests of various kinds related to industrial training. Because of the interest of engineers in drafting work, a contest in skill for drafting apprentices is suggested.

Such a contest may be conducted by a local committee, and if given extensive publicity will be very effective. Another possibility for the local branches is to give an award for the best paper written by an engineer on an assigned subject in the field of industrial training. The successful papers might be read before meetings of local branches of the Society. Also local branches might award a medal or cup every year to the corporations in their respective communities which have made the greatest advance in industrial training in a given year. Such a contest might be the most effective of all, but would need to be more carefully directed than the others.

Contests of this kind could be carried on without extensive study or research, and experience in similar contests conducted under other auspices has proved that they are very effective for purposes of publicity. Through contests the influence of the Society would force attention to the problems of industrial training on those who are most directly concerned.

IN SPITE of many notable exceptions, engineers as a rule give little thought to the young men who are growing up in industry and learning industrial work. Of course, it is fashionable to patronize a young engineer and help him over his early strenuous years, but such patronage is something quite different from an understanding of the need of American industry as a whole for trained young men, and young engineers are quite different from the type of young man with whom we are now concerned, that is, young men who do not graduate from a technical college, but who hope to become mechanics, technicians, draftsmen, or highly trained, highly skilled experts of any kind. A good example of this attitude is the case of a well-known engineer who recently made the statement that efforts in behalf of industrial training were a waste of time and energy. He said there was no need for all this activity because mechanics and skilled men of all kinds should be hired in the open market. He had never thought about the problem long enough to reach the conclusion that if there are mechanics in the open market somebody must have trained them.

However, it is no longer possible to hire skilled mechanics at will. In February, 1927, when business was rather dull and 40,000 men were reported to be idle in Milwaukee, a prominent oil-engine manufacturer received a considerable order, and wanted to engage 65 high-grade mechanics. Among all those unemployed men, it was impossible to find the 65 mechanics or anywhere near that many. The employment manager of the corporation visited other cities for a period of several weeks in a search for skilled men, but failed to assemble the required number. A certain foundry managed to get a little business in 1924, which was also a year of business depression, and was unable to engage 18 first-rate foundrymen, although the number of unemployed in the city at the time was as great as it had ever been. Our industries are very clearly confronted with the responsibility for training their own mechanics and experts.

Probably the majority of mechanics are foreign-born and foreign-trained men. American industries have been depending upon European apprenticeship systems for training, and the new immigration laws have cut off this source of supply.

Industrial Training a Proper Function of the Society

At first sight, this may not appear to be a problem of the engineering profession. However, the welfare of the profession depends upon the progress of industry, and to this extent, at least, engineers are concerned with these problems of industrial training. Moreover, the constitution of the Society specifies that two of its purposes are to broaden the usefulness of the engineering profession and to advance the standards of engineering. Both of these purposes may be accomplished in part through increasing the effectiveness of manufacturing industries by a higher development of skill on the part of those who work in these industries. The very existence of the Committee on Education and Training for the Industries is proof that industrial training of this kind is a proper function of the Society. The influence of the Society in industry is tremendous, and energetic promotion of industrial training by the Society will probably do more to develop the movement than can be accomplished in any other way.

Although much has been done in apprenticeship in various centers and individual industries, a mere beginning has been made, and very few manufacturers, comparatively speaking, have given the question much attention. Accordingly, it is suggested that the Society could probably do the most good by giving the industrial training movement the widest possible publicity.

The question will be asked, just how can the Society give wider publicity to this movement? It can be done in many ways; for instance, by contests of various kinds. Human nature seems to crave competition and striving. Throughout the history of mankind, contests have been held and prizes awarded, not only in athletics, but in almost every branch of activity. Would it not be well to take advantage of this human trait for the promotion of industrial training? Since it is important to bring the subject of industrial training before manufacturers in all parts of the country, local branches of the Society might well hold contests in their respective communities.

Contests in Skill and Workmanship for Drafting Apprentices

The draftsman gives the first concrete existence to the engi-

[1] Vice-President and Works Manager, The Falk Corporation. Mem. A.S.M.E.

Presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

neer's ideas, and certainly works closer to the engineer than any other tradesman. For this reason engineers are probably more interested in drafting work and draftsmen than in any other trade or tradesmen. Accordingly, a contest for drafting apprentices conducted by the local branches of the Society is suggested and this contest might well take the form of a competition in skill and workmanship.

A committee of engineers can be placed in charge, and experience has proved that the duties of such a committee would by no means be arduous, and moreover the work would be intensely interesting. The first task of such a committee is to become familiar with the type of contestants. College graduates should be excluded from the contest, which should be restricted to regularly indentured apprentices, that is, apprentices who are following a formal course of work for training in compliance with a definite agreement in writing. Since the Society seeks the promotion of organized training in industry, nothing can be gained by holding contests for any and all young men who happen to be working in a drafting room with the idea in mind of advancing themselves, nor should such young men be admitted to compete with those who are following a formal course. In other words, the Society should not encourage haphazard, slipshod methods of training draftsmen. A few hours in a number of drafting rooms spent in conversation with various apprentices will undoubtedly make the members of the committee sufficiently familiar with the type of men who are to participate in the contest. The purpose of this acquaintance with the young men concerned is to learn their capacity and to plan a contest which shall be appropriate.

The committee can select the problem or problems for the contest. These may be work in actual drawing or design, or the solution of problems in applied mathematics or science, or a combination of both. The design problem may well be a simple assignment such as drawing an ordinary pedestal bearing, given the shaft size and revolutions, or a flanged-faced coupling, given shaft size, revolutions, horsepower, and any other data which may be necessary. Because participation in such a contest will involve interruption of regular work, it would be well to limit the contest problems to a single day's work. The success of such a contest will depend upon the support of local manufacturers, and care must be taken not to antagonize them in any way.

It will be necessary to determine how many will participate, whether one shall come from each plant, whether representatives may be sent in proportion to the total employment of drafting apprentices or whether all drafting apprentices in the community may compete. A number of other details must be worked out such as a place in which to hold the contest, a system of identification so that the judges shall not know the names of those who participate, supervision of the contest, announcement to employers, provision of material and equipment, and other matters.

Before the contest is completed the committee will need to establish standards for the judgment of the work. Such standards would include proper design, dimensions, neatness and arrangement, sufficiency of views and similar points for the actual drawing, and correct solutions and evaluations of each problem in mathematics or applied science. The judges should be selected and instructed carefully, and the board of judges should include a number of engineers who are not members of the contest committee. Obviously the person who arranges the details, and to whom the contestants' identification numbers are known, may not be a member of the board of judges.

Extensive Publicity Is Necessary

In view of the purpose of the contest, the names of the successful contestant, or contestants in case more than one prize is available, should be given the widest possible publicity, and the prize or prizes should be awarded with much ceremony, preferably in the presence of as large and distinguished a gathering as can be assembled for the purpose.

Of course, a trade contest for drafting apprentices is merely one possibility. Such a contest cannot be carried out in most manufacturing localities for the reason that drafting apprenticeships are still somewhat unusual and there are but few communities in which they have been established. It might be advantageous to hold similar contests for apprentices in other trades. However, other contests, not of a trade nature, may easily be held and will prove to be of great benefit.

Annual Prizes for Papers on Industrial-Training Subjects by Engineers

Local branches of the Society may offer an annual prize for papers written by the members on some phase of apprenticeship. Such a contest might possibly be still more effective than a trade contest for the reason that a considerable number of engineers would be required to devote much thought to the subject of apprentice training, and their studies would force them to reach important conclusions which they would not otherwise attain. The contest would thus have the very much desired effect of calling the attention of engineers to the questions of trade training for young men.

It might be well to rotate the contest year by year through various classes of membership. In one year, the contest might be held for full members, in another year for junior members, in another year for undergraduate members, and after sufficient interest has been aroused, it might be interesting to hold a contest for members who are themselves the heads of business organizations. Subjects suggested for such contests are:

1 Why apprenticeship concerns the mechanical engineer
2 The need for apprenticeship in American mechanical industries
3 How apprentices may be effectively trained in this community
4 American young men and industrial work
5 Highly skilled men are still required in our industries.

A committee can handle such a contest very much as was suggested for the drafting contest. A number of details need to be worked out, such as to determine who is eligible for the contest and how eligibility is to be determined, the time limit for writing the papers and the length of the papers, a system for identification, publicity, the form of the manuscript, and other points.

A board of judges must be selected carefully, and the prizes should be awarded with much ceremony at some important gathering. It might be desirable to have the prize winners read their papers at such a meeting and permit those present to discuss them. Possibly, the best papers written in these contests could be included in a program for a meeting of the American Society of Mechanical Engineers and published in Mechanical Engineering.

Award to Local Corporation Which Has Made the Greatest Progress in Industrial Training

Still more effective would be the awarding of a cup or medal by the local branches of the Society to the corporation in the community which has done the most effective work or has made the greatest progress in the training of apprentices in the course of a year. Such a contest would have the distinct advantage that the competitors would be those who can do the most in the development of apprentice training. Regardless of promotion by various agencies, the fact remains that it is the employers who must actually engage apprentices and train them.

For such a contest it will be necessary to set up very carefully a schedule of points or standards for the selection of the winners and to evaluate these points as correctly as possible. The following are a number of points or standards which might well be included in the judgment:

1 Extent of organization of training courses, including the completeness of work schedules
2 Extent of training in the organization, that is, whether established in one or two departments or in all of them
3 Proportion of indentured apprentices who have graduated in a given period
4 Methods of shop instruction
5 Methods of school instruction
6 Methods and extent of general supervision
7 Number of apprentices in proportion to skilled mechanics.

Because the identity of the contestants cannot be hidden, a considerable number of judges need to be engaged, and they must act independently and report their findings on a suitable form on which the points or standards are included and assigned their corresponding evaluation.

The contest can be announced in advance by inviting corporations to participate, whereupon the competition would be limited to those who have entered, or the committee in charge and the judges can make from some reliable source a list of corporations who are entitled to participate and can visit them for the purpose of studying their work.

The success of such a contest, as of the others suggested, will depend almost entirely upon full publicity both before and after the contest, in newspapers, trade and technical papers and magazines, and in private publications of the various corporations which may have them.

Maximum Results From Minimum Effort

A distinct advantage of all these contests is that through them the Society can exert much influence without the heartbreaking labor of extensive research and study. Any one who has occasion or takes the trouble to read the reports of various technical committees of the Society can see between the lines a story of countless hours of painstaking investigation, countless additional hours spent in arranging and rearranging data and facts, followed by cautious progress toward conclusions, interrupted by frequent readjustment and much discarding. The committee work involved in contests would be much simpler. A few hours would be required to draw up the regulations for holding the contest, and these could be based very largely upon the regulations for existing contests of a similar nature already in force. A few more hours would be required by the committee for arranging the contest and the judges might be required to devote a day or two to their work. However, all the work would be comparatively simple, and ought to be enjoyed very much by those engaged in it.

If local contests of this kind are successful, there is no good reason why the Society should not sponsor national contests, in which case the local contests might be standardized and would serve as elimination contests for the national event.

Similar Contests Under Other Auspices Have Been Successful

Contests of this kind have been proved practical by experience. Successful competitions in the writing of papers have been conducted by a very great many agencies and institutions of different kinds. Some of these have been carried out on a national scale and have attracted much attention. The awarding of a prize to the corporation in the community which has made the greatest advances in industrial training for young men presents some difficulty so far as the correct selection of the prize winner is concerned. However, medals and awards are given annually by the Society under conditions equally difficult. The success of such a contest will depend very largely upon the prestige of the judges.

Trade contests present no great difficulty. For a number of years the Milwaukee branch of the National Metal Trades Association has conducted contests in trade skill for apprentices in machine work, drafting, pattern making, and iron and steel molding. These contests have been more and more successful in succeeding years. Successful nation-wide contests have been conducted by the American Foundrymen's Association during the last four or five years for apprentices in iron and steel molding and in pattern making. Elimination contests for apprentices in these trades are held by local foundry and manufacturing associations, and the final judgment of the castings and patterns, with the announcement and awarding of prizes, takes place at the annual convention of the association. The Milwaukee contests in pattern making and iron and steel molding have been preliminary to this national competition of the American Foundrymen's Association.

The popularity of contests of all kinds at the present time for purposes of advertising and publicity indicate that they are extremely effective for such purposes. Favorable results may be expected from the holding of contests by the Society of the kind suggested. The contests will attract general public attention and will make the chief officers of corporations, shop officials, technical engineers, and others appreciate the importance of organized training for young men who hope to work in the industrial field. Trade contests stimulate great interest and rivalry on the part of the apprentices themselves. But the most important advantage of all would be the prestige which organized industrial training would derive from the support of the Society. The standing of the Society is such that all manufacturers and all technical people are practically forced to take seriously any movement which the Society sponsors. It is extremely necessary at the present time that manufacturers and business men take the training of young men for industry much more seriously than they have in the past.

Discussion

Warren G. Findley.[2] The author has presented his project as a means of attacking a problem which faces American industry. The writer would like to call attention to the way the project can contribute to the solution of another problem, which, for want of a better name, he has called "the problem of the failure."

Each year every school is confronted with the question, "Whom shall we admit to the first-year class?" Various answers to this question are given in the various systems of admission used, but with one invariable result: some are selected; others are refused admission. These last have "failed." They feel they have failed. And that, from the psychological point of view, is equivalent to saying that they have failed. Letters, telephone calls, and personal visits ask, "Wherein did I fail?" and "What shall I do?"

Both questions require answers. It is impossible to waive all responsibility and say, "We offered you a chance and you failed to make the grade; that is the end of that." We say, "We regret to inform you that your test rating was too low to warrant your admission. You may try again next year." In a school which limits its enrolment it may be possible to soften this by stating that only a certain number can be admitted and the individual was refused because too many better prospects applied. This only disguises the real reason, for in such schools

[2] Assistant in Psychology, Cooper Union, New York, N. Y.

the limitation generally guarantees that theose selected are of satisfactory ability to make a go of the curriculum offered. To borrow a physical concept, a relatively static equilibrium exists between the abilities of the best 100 applicants of any year and the demands of the curriculum. However, regardless of how we break the news to him, our rejected candidate is a failure until we answer his second question with something more promising than permission to try again.

We should like to be able to say, "You do not show great promise of success with our engineering curriculum. We should suggest that you try this other kind of work." Some optimists in the field of vocational guidance feel that they can make such statements on the basis of certain aptitude tests. Such tests are still in the experimental stage as far as giving occupational guidance is concerned. However, if such a program as Mr. Falk has outlined were adopted, we could say, "You do not show great promise of success with our engineering curriculum. We should like to call your attention to a competition sponsored by The American Society of Mechanical Engineers in engineering drafting."

At this point we should be offering an alternative. We should no longer be leaving candidates worse, for their feeling of failure and inferiority, than we found them. It would certainly be a step forward over our present procedure if only a handful were to take advantage of this alternative. It now becomes a question as to whether we should be contributing significantly to the Society's program.

This last summer 1149 individuals took entrance examinations for the engineering courses at Cooper Union; 303 were admitted; 846, or approximately 74 per cent of them, were rejected, as described. What were those rejected men like?

By their appearing for examination, they indicated their interest in engineering. It may not have been an intelligent interest based on a thorough understanding of the nature of an engineering course. In the cases of a particular individual it may have been based on anything from hearing that engineering schools train men to build the impressive buildings and bridges seen every day to the applicant's having been pronounced a future Edison upon repairing a doorbell at an early age. The fact remains that a potential energy exists in the persons of 846 men who desire to become engineers.

When we reject these men, as we now do, this energy is gradually dissipated. The program before you offers an opportunity to harness some of this energy in a place where it is needed. If any of these men have the ability to acquire the skill called for, they should be better than average prospects.

The case for men rejected at entrance applies with the same force to men who flunk out. Selection of men for admission is meant to separate the sheep from the goats; in practice it becomes the matter of letting in as few goats as possible among the sheep. These few cannot do the work and consequently fail. And there are among these failures some who show a marked ability over the drawing board, while unable to carry the rest of the curriculum. These last fit the specifications of the contest exactly.

The author has offered one specific suggestion, a competition for drafting apprentices. He has gone beyond that and indicated ways of getting further suggestions through essays on industrial training by engineers and by a competition among industrial concerns for progress in industrial training. They who have the problem of admissions hope the plans prove feasible.

WILLIAM J. DONALD.[3] There can be little doubt about the need for the training of manual workers in American industry. Until the last few years America has been depending upon immigration for her supply of trained workers. Immigration restriction is undoubtedly cutting in on the new supply that we were accustomed to receive year by year. Actually, however, the curtailment of skilled immigrant workers has not been in proportion to the curtailment of the total number of immigrant workers, because skilled workers can more easily get within the quotas than unskilled workers.

This is a subject of complaint on the part of many European industrialists and also here in America, and their complaint is rather pointed, despite the conditions of unemployment abroad. No country and no industry is keen to lose its best workers.

The facts such as the author presents regarding the dearth of skilled workers could be amply supported by evidence from any other quarter. The attack on this problem may, of course, be made as the author suggests, by stimulating the interests of the apprentices themselves. One may well doubt, however, whether an approach to the apprentice himself would be nearly as effective as contests or other devices directed toward the executives and the industries themselves. It has become generally accepted that accident prevention becomes more effective when the efforts are concentrated on the foremen and other supervisors rather than on the multitude of manual workers.

Similarly, there is a distinct trend in industrial training toward concentrating on the ability and the responsibility of the foreman to train rather than directly on the apprentice himself. Training departments which undertake to do the whole training job can never more than skim the surface. A training program that contemplates the training of all supervisors to train their own workers, whether apprentices or those who have completed an apprentice course or semi-skilled or even unskilled workers, will achieve far more than the best training department can achieve alone.

Efforts to encourage education and training for industry will accomplish far more if the contests and awards are directed toward industry itself rather than toward the apprentices. Local contests which would recognize the training work of a particular company or companies would stimulate a degree of interest far in excess of contests which would recognize the skill of a few individual apprentices.

Essentially, training is a responsibility of management, and the solution of the problem of competent skilled workers will never be achieved as long as attention is directed only toward the workers.

The preparation of a schedule of points or standards for the selection of victors in corporate contests will no doubt arouse a great deal of dispute.

The author's schedule suggests four very interesting points, but there are other points which it seems will need attention as well. Some of them are as follows:

1 The extent of the effort to train supervisors to train
2 The proportion of supervisors who are coming under the influence of such a teacher-training program
3 The effectiveness of the formal set-up for training foremen to train.

There is a question, too, as to whether all of the attention should be concentrated on formally indentured apprentices. It is splendid to provide for a comprehensive period of apprenticeship that will carry younger workers through to the acquirement of a satisfactory degree of skill, but it is also important that semi-skilled workers should receive training. There is always a danger that a formal apprentice-training system for so-called indentured apprentices may direct attention away from the less formal training procedure for other workers.

[3] Managing Director, American Management Association, New York, N. Y. Assoc. A.S.M.E.

WILLIAM H. SNIFFEN.[4] The Chairman of Education for the Bridgeport Local Section of the A.S.M.E. says: "The contests referred to in the paper by Mr. Falk are undoubtedly a good method for furnishing an incentive to men working in the lines mentioned. This would be most applicable to industries where men are involved in a multiplicity of work of the same nature, and it would be a very good thing to have developed a plan for concerns that could take advantage of it."

The writer, long an executive in industry, and with experience in handling men, women, boys and girls, feels that it would be an inspiration and an incentive were any or all of the four points brought out in the preamble of the article put into effect. Too often there is an advance given to some one because of influence rather than to encourage those less fortunate and who have inert ability to perform what may appear as unusual.

The greatest element to success, and one that is often overlooked by the executives in industry, is the human element. This most important element to encourage the employee to produce quality as well as quantity is promoted through interest in the welfare of the employee in the plant and at home. The results attained are beyond the belief of some executives; yet with this contact and the other incentives set forth they will benefit employee, employer, and the public at large.

CHARLES F. BAILEY.[5] The author's suggestion for arousing interest in apprentice training should preferably be tried in the larger industrial cities and communities where there are groups of apprentices engaged in more or less similar work. In the smaller towns or cities where the industries are small and widely separated and the number of apprentices is small, the efforts required for success would be much greater owing to the lack of acquaintance and close contact. In such localities some other method might be more productive of stimulating interest.

The writer approves of the suggestion for an award for the best paper written by an engineer on an assigned subject, for the best drawing made by an apprentice, and for recognition of the corporation which has made the greatest advance in industrial training in a given year. He recommends the valuable aid provided by the Smith-Hughes Act designed to advance vocational training and education. Experience has proved this to be of great help and most satisfactory. At first it was feared that this might curtail the authority of the company with regard to the instructors, but such fears have not been realized.

In the art of shipbuilding many trades are involved, and apprentices are now enrolled in 19 or 20 different trades. In addition a number of other trades are being taught in which there is not sufficient training content to warrant an apprentice course. Under the Smith-Hughes Act foremanship training is also being carried on. At present the Dean of the Division of Economics at William and Mary College conducts a weekly round-table discussion on economics of foremanship, psychology, etc. There were 27 training instructors attending this course.

Under this apprentice training the boys are given the finest opportunity for individual progress. Some are carrying on, in addition to apprentice work and school class work, correspondence courses of study and doing, work assigned under direction of the supervisor. For these outside studies the boy is given additional credits. One apprentice whose home is in Pittsburgh, where he attended high school for about three years, came to Newport News to enter as an apprentice to learn shipbuilding. He has served two and one-half years in the yard, now is in the hull-drawing room, and in addition to his apprentice work and class work is taking college extension work in evening classes presented by William and Mary College.

In order to promote apprentice training it is first necessary to sell it to the company executives. This should be the aim of the Society, as it is the foundation required for success. A management in hearty, active sympathy with such training will foster it in many emphatic ways.

Next in importance is the personality of the apprentice supervisor. This should be outstanding, coupled with a human sympathy, liking, and admiration for the young men. Such supervisors and instructors are the only ones to be entrusted with this training.

Apprentice-training work when heartily fostered by the management and properly set up becomes more and more attractive and valuable to the company, to the apprentice, and to the community. Later it almost partakes of recreation for the sympathetic executive as he sees the brightest young men advancing from year to year and then becoming honored and trusted employees, foremen, supervisors, and superintendents. Outstanding examples include a superintendent of a large and important division in the works, a general foreman of the large shops covering machine work and engineering, a coppersmith foreman, electrical assistant foreman, and an engineer in charge of piping division. Half of the best draftsmen in this division are former apprentices. There are numerous outside examples of young men sailing at sea in ships reconditioned or built by the company, including the "Leviathan" and other important vessels driven by steam turbines, turbo-reduction gears, electrical propelling machinery, and Diesel engines. A city manager is a former apprentice.

If the training is made attractive and beneficial to the apprentices, there will probably be more applicants than can be accommodated. Such training should include classes for each apprentice, with two three-hour periods weekly, and these should be during working hours and on the company's time, the apprentices being paid for this work the same as for shopwork; the studies to include mathematics, physics, chemistry, laboratory work, English, economics, mechanical drawing, etc. These classes can be worked into very attractive periods. It is more and more important that applicants be selected from the better class of boys, with some high-school experience, if not graduates. Preliminary tests should be given, with a thorough physical examination and intelligence tests. It is realized that after spending four years in training only the brighter minds and best of bodies should be selected.

The mental attitude and morale must be constantly watched to keep interest and ambition, and care should be exercised as to the man with whom the apprentice works. This is one reason for selecting the training staff largely from former apprentices, chosen for their personality and moral tone.

The training course must be properly planned. By what is known as the block system the executive knows daily at a glance the exact standing of each individual. The block system can also be applied to the training of special-purpose men by taking different blocks and training in these only. Such training is often necessary in large shops where the skilled labor supply is curtailed.

In a large organization a boy after graduation is in danger of becoming lost to notice without the attention and the interest of a personnel superintendent.

All apprentices and the training staff are invited to a monthly foremen's lecture, where they see and hear the outstanding men in higher positions in the works.

In addition to instruction in classrooms and in the shops, the following outstanding points in apprentice training have a marked influence in building up morale and making the work successful and attractive:

[4] Sales Engineer, Connecticut Ice Machine Company, South Norwalk, Conn. Assoc-Mem. A.S.M.E.

[5] Engineering Director, Newport News Shipbuilding and Dry Dock Company, Newport News, Va. Mem. A.S.M.E.

The adoption of self-government administered by an honor council.

Appointment of an athletic committee, the president of which is president of the apprentice association.

Organization of an apprentice band.

Apprentice Savings Association.

Public award of letters and honors earned.

In all training the application of the Richards Formula should be constantly in mind, wherein E = effective training, which involves and is proportional to $M + T + I + J + Mo$.

M	= manipulative skill	Shop		Hand
T	= technical knowledge	School		Head
I	= information (auxiliary)	School		Head
J	= judgment (trade)	School		Head
Mo	= morale	Sport		Heart

The Society can, if it will, promote and spread an active interest in the value of apprentice training, both to the worker and to the industry. It is encouraging to find a younger man like the author who has seen the importance of the movement and whose heart is in it. The influence and enthusiasm of a few men of this stamp will do much to promote a realization of the need of apprentice training throughout the country, and if this need is realized steps will be taken to meet it.

J. J. Morgan.[6] The author's plan seems to have been worked out carefully, and no doubt it will be found as successful in other large centers as it has been in Milwaukee. It seems desirable, therefore, that it should have been given the publicity and standing which will result from its presentation.

A description of work which is being done along this line in the gas industry by the Home Study Department of Columbia University may be of interest. In October, 1925, a course on manufactured gas was offered at the request of the Committee on Education of the American Gas Association. Instruction has been along practical lines in order to satisfy the requirements of men in the industry seeking further knowledge of gas company operation. It consists of 24 lessons covering the technical phases of the production, distribution, and utilization of manufactured gas, and treating also such allied subjects as safety, accounting, rates, the sale of gas, and public relations. The instruction assumes that the student has a high-school education or its equivalent and a knowledge of elementary chemistry and physics, but a majority of the men taking the course have had a college education.

Instruction is given by means of a text[7] written especially for the course and a syllabus giving (1) an outline of the subject matter, (2) the text and supplementary references, (3) a discussion of the subject matter and advice to aid in its study, (4) questions and problems for the student's notebook to lead him to definite conclusions, and (5) examination questions to test the student's mastery of the lesson. The examination papers are returned to the students with a letter explaining errors which have been made and offering suggestions as to the mastery of the subject matter.

[6] Associate Professor of Chemical Engineering, Columbia University, New York, N. Y.

[7] "Manufactured Gas, a Textbook of American Practice," by J. J. Morgan.

It is planned that each lesson should require 20 hours of actual work by the average student, but many students spend much more time than this.

The American Gas Association cooperates in the preparation and presentation of the course through an Advisory Committee of four leading gas engineers who review all the material for the course and act as general consultants in its conduction.

Since its beginning in 1925 some 1400 men have been enrolled in this course, of which number a few more than 400 have completed the work. It is probably the first home study or correspondence course given by a university in cooperation with the national association of a major industry.

Author's Closure

It is fortunate that Mr. Findley has pointed out the value of apprenticeship and industrial training for the great rank and file of young people for whom higher education is impossible for one reason or another. Apprentice training is really an attempt to apply in the field of industry those same principles of general opportunity which have made public education effective in the United States. Mr. Findley discusses applicants for college training who have failed to pass the entrance examination and suggests the possibility that these young men might enter the drafting field through a contest in drafting of the kind described. Perhaps it has not been explained clearly enough in the paper that these contests are intended only for apprentices who have been in training for some time. They would therefore not be open to beginners. It may well be that contests might be held as an entrance requirement for drafting apprenticeship, but we have had no experience in this direction, and while we admit the possibility of the plan, we are not in a position to endorse it.

Mr. Donald's remarks provide an opportunity to mention that experience in Milwaukee metal-trades plants indicates that the entire apprentice-training program, as well as the training of other workers, centers around foremen, department heads, and special instructors who may be appointed in various departments. The function of the training department is to direct the work and make all necessary arrangements, but the actual training, the actual imparting of trade knowledge and skill, must necessarily be done by those under whom the apprentices and workers are employed. In the paper the assumption was made that effective apprenticeship implies a qualified and trained corps of foremen and department heads. Perhaps this was taking too much for granted, and Mr. Donald's emphasis on the point is appreciated.

It has been the author's experience that contests for apprentices stimulate as much interest among foremen and department heads as they do among apprentices themselves. At the same time, competitions for employers and supervisory persons would also be very effective.

Mr. Bailey questions the advisability of holding competitions of the kind described in smaller communities or in communities with a large number of small industrial establishments, for the reason that sufficient coordination between these elements may not exist. This suggests the question, Would not the holding of a contest create the very cooperation which is needed for effective community apprentice training?

MAN-52-5

Management of Service Departments—Budgeting and Wage Incentives Applied to a Large Organization

By WILLIAM B. FERGUSON[1] and TOM H. BLAIR,[2] NEWPORT NEWS, VA.

The organization and the management of the service departments in a large plant with over 6000 employees doing a great variety of unstandardized work of fluctuating volume and spread over an area of 140 acres present many difficult and complicated problems in comparison with similar problems in the usual manufacturing establishment. After the productive or operative departments in the Newport News plant had been reorganized and modern methods of planning, scheduling, production control, cost control, and wage-incentive plans had been put into effect over a period of about five years, it then became possible to undertake further improvements in the staff and service departments with respect to better organization and the training of executives and employees, and the measuring in some way, directly or indirectly, of the value of the service rendered or the output of these service departments; and finally the applying of bonus plans or other wage-incentive schemes to reward the employees in these service departments, with over 700 men and women, for improved efficiency. The methods described are the result of preceding study and preliminary work for over a year and represent the simplest forms of wage incentive that seemed practicable to apply to a large plant of this character. The first service department was put on a bonus system in April, 1928, and there resulted a net saving during the first 15 months (that is, about four months after the last service department was put on a bonus system) of about $175,000 for the whole plant. The simple methods used have created great interest on the part of heads of departments and employees. The main feature is that an opportunity has been and can be offered to all employees in all service departments for increasing their earnings in proportion to their results and thereby increasing the net earnings of the company to a much greater degree than has probably ever been appreciated.

MANAGEMENT of service departments in any large plant, especially a very large plant such as will be described, and application of scientific methods of study and analysis and cost control are much more difficult than applying scientific management to ordinary manufacturing or productive departments where the work can in a measure be standardized. In productive or operative departments as distinguished from service departments, it usually is possible after thorough study and analysis, and after the education and training of executives, to put into effect, with the support and interest of all concerned, the best methods of modern management in proper sequence, beginning with drawings and material supply, material control and distribution, planning, scheduling, and routing, cost control and cost budgeting, and finally wage-incentive plans, either piecework or bonus or premium methods of payment based upon definite and measurable production or output. This last step, that of the fair application of wage incentives or some scheme of equitable reward to individuals or groups for services rendered, may be looked upon as the final stage or step in progressive management which insures a continuous and perpetual interest on the part of all employees in getting better production and increasing the prosperity of themselves and their employers. Therefore the practical development and application of fair rewards or wage incentives for the large number of men and women engaged in service departments is a forward step toward the mutual confidence and success of employees, management, and owners, and marks a new era in industrial management, because of this opportunity for reward being offered to those employees whose work cannot be definitely measured or standardized in the ordinary sense, who never before have had a real opportunity for increased earnings based upon their individual or group efforts and results.

Unusual Conditions for Service Departments to Meet

The plant selected for this discussion is the largest shipyard in America, the Newport News Shipbuilding and Dry Dock Company, on the James River in Virginia, employing at present about 6400 people, of whom about 1000 are employed in what will be called "service departments," which includes general office work, drafting work, accounting and cost departments, material supply, storage and transportation, time-study departments, and a great variety of other functions that are shown in the upper part of the chart, Fig. 1, which is a skeleton organization chart of departments whose heads report to the Production Manager or are coordinate with the heads of departments under the Production Manager. The operative departments are under four superintendents, shown in the lower half of the chart. There are about forty separate operative departments, having over 5000 employees, including practically every craft or trade that has to do with metalwork or woodwork. The plant has its own foundries making iron, steel, and brass castings. It also makes most of its own forgings. It therefore has smith shops and several machine shops. From the nature of its products and from its location the plant has to be practically self-contained; that is, it does practically all of its own work, including piping and sheet-metal work, coppersmith work, and all woodwork. In the woodwork departments alone there are about 700 employees. Since the principal business of this company is building and repairing ships, the greater part of the force is at work in the open or outside of the sheltered shops, either on the ways, in the dry docks, or at the outfitting piers. In addition to building and repairing ships the plant is also engaged in hydraulic work, making water wheels and hydraulic accessories as well as hydraulic structural work such as flood gates and trash rakes. The plant also does an extensive miscellaneous jobbing business, especially in forgings and

[2] Head of Time Study Department, Newport News Shipbuilding and Dry Dock Company.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

castings of various kinds. The character of the work itself requires that the shops and other facilities extend over an area of about 140 acres, which gives rise to many unusual problems in plant engineering, transportation, storage of materials, and materials handling methods. (See Fig. 2.)

Practically none of the work in the plant is duplicate work, and therefore by its very nature it cannot be standardized nor can repetition methods be used as in ordinary manufacturing. The situation with respect to the management of service departments in particular is complicated by all these conditions and also by the fact that practically all work is contract work (that is, no work can be manufactured for stock) and by the further important fact that the ship-repair business is somewhat of a seasonal business, with a large rush of work at various times and at other times this work being slack. This gives rise to somewhat violent fluctuations in the volume of work and the total number of employees, which of course affects the cost of the service departments and makes it difficult to fix a budget for departmental cost. During the last two years the force has been as low as 4400 employees and as high as 6600.

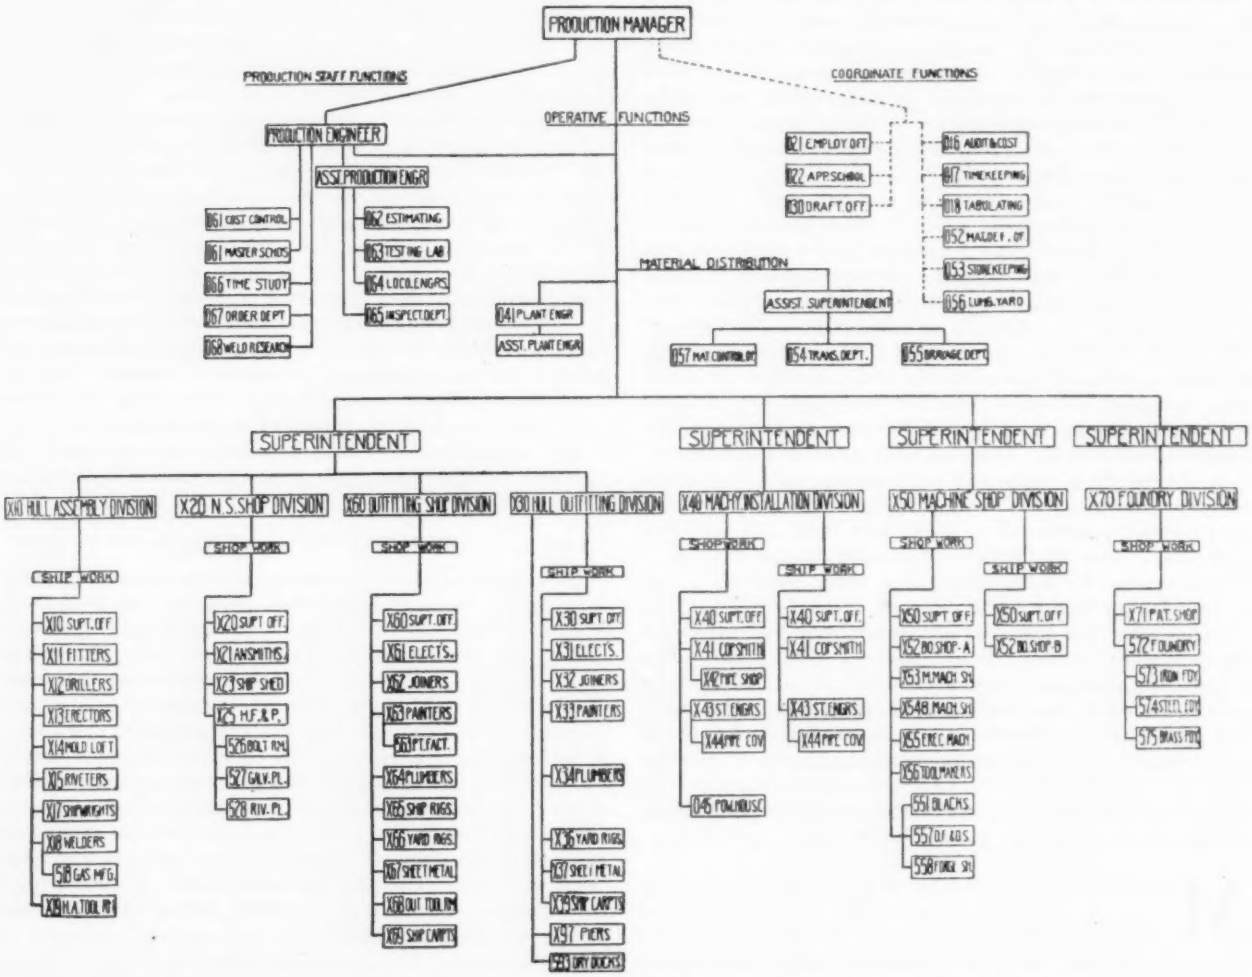

FIG. 1 ORGANIZATION OF PRODUCTION FUNCTIONS, SHOWING SHIP WORK AND SHOP WORK SEPARATELY

Group bonuses can be applied to the work of service departments where one cannot measure separately the output of individuals on account of the great variety of functions performed by nearly every person in these departments. This condition in this large plant becomes apparent from a study of the functions when given in detail, as set forth in the "Supervisors' Manual," extracts from which are given in Appendix No. 1, covering briefly the main functions of the Production Division (under the Production Engineer, 88 employees on bonus plan), Time-Study Department (34 employees), Order Department (18 employees), Employment Manager (10 employees), Plant Engineer (25 employees), and Inspection Department (under Production Engineer).

The foregoing variable and uncertain factors make it necessary to establish, by study of previous cost records of service departments, some kind of budget or bogey for the overall cost or output of these departments in quite a different manner from that in which it can be established for ordinary manufacturing plants making a uniform product of either standard or predetermined volume. The first thing, therefore, to be described will be the method of setting budgets or bogeys for the 23 service departments, all of which are now on some incentive system, based upon these budgets. Each budget has been developed in the form of charts or curves based upon the fluctuation in the working forces or in the amount of service required by each service department.

INCENTIVES AND BUDGETING

TRANSPORTATION SERVICE AND MATERIALS HANDLING

To illustrate exactly how this has been done, there first will be

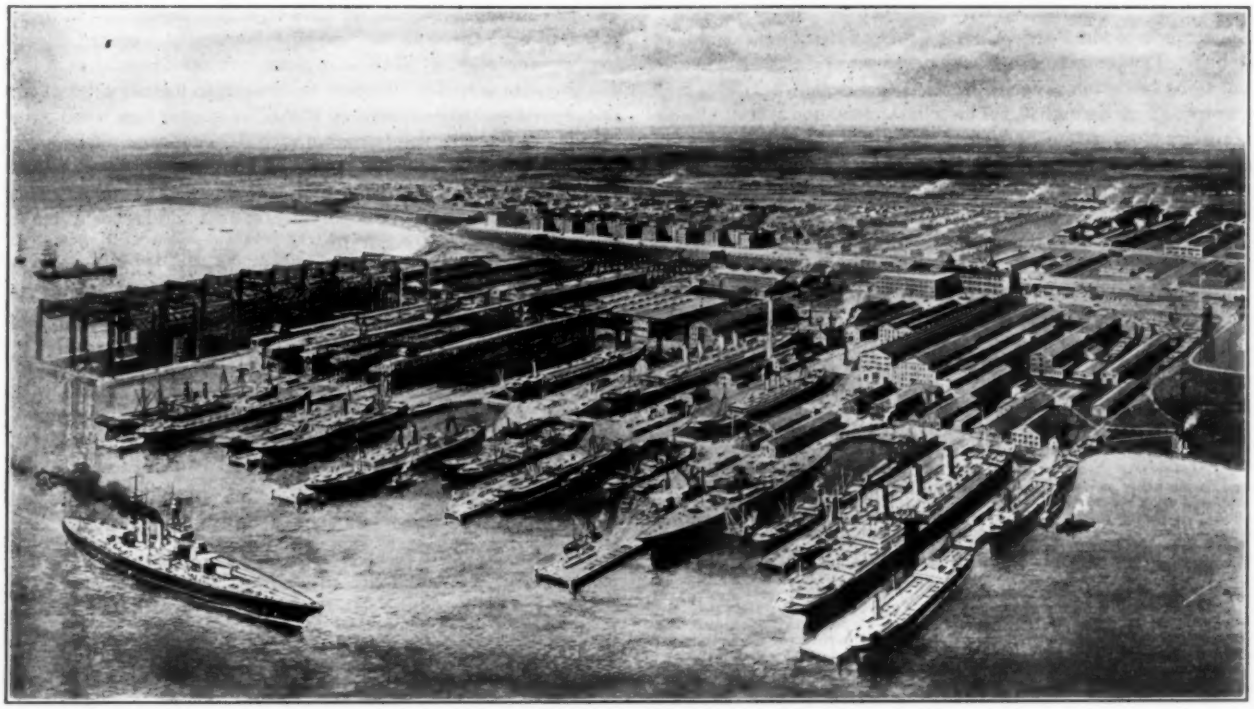

FIG. 2 VIEW OF NEWPORT NEWS SHIPBUILDING AND DRY DOCK COMPANY'S PLANT

selected one of the most difficult departments to manage economically, the Transportation Department, whose general duties are given under 16 main headings, as follows:

1 Render switching service, i.e., shift cars from interchange to unloading points in the yard and returning same to interchange when empty. Shifting all cars from one location to another in yard. Transporting all materials too heavy to be handled by trucks and trailers
2 Furnish crane service for handling materials that are not in reach of stationary gantry cranes
3 Load and unload foreign cars out of radius of stationary or gantry cranes. Furnish hand labor for loading and unloading cars, except where labor is furnished by other departments
4 Hostle all locomotives and locomotive cranes
5 Make minor repairs to cranes, locomotives, and flat cars
6 Inspection of foreign cars on receipt and release, repairing any minor damage done to same while in yard
7 Record and report fuel deliveries made to various places in yard
8 Furnish labor to work in dry docks to assist yard riggers in emergencies
9 Furnish steam for ships, such as steaming tanks, condensers, heating boilers, and heating ship
10 Yard cleaning in certain zones
11 Yard grading
12 Maintenance of yard tracks, lawns, surface drains, and retaining walls
13 Salvaging, classifying, and loading for shipment all yard-scrapped material
14 Supply foundry with requirements of scrap
15 Bagging coal sold to employees
16 Record and report deliveries to interchange.

The number of employees engaged in the foregoing services has varied from 150 to 75 during the last four years.

As will be seen from the foregoing duties or functions, the Transportation Department is a real service department. To perform this service, it has the following equipment:

5 locomotives, various types
16 locomotive cranes, 10 to 125 tons capacity
78 flat cars, 8 different types
25 miscellaneous cars, 9 different types.

There are approximately 14 miles of railroad track in the plant.

CHANGE FROM PIECE WORK TO BONUS PLAN

Although certain classes of work in this department had been placed previously on an incentive basis by the establishment of standard piece-work pieces wherever possible and subcontracts for certain other jobs where practicable, yet at no time was it possible to have the efforts of more than 35 per cent of the department's personnel influenced by some kind of a wage-incentive plan. While such work as unloading coal, coke, pig iron, foundry sand, steel plates, and other general work which lends itself to an exact quantitative or physical measurement of unit output could readily be done by piece work, there remained a much larger part of the department's regularly performed duties that could not be included in any kind of piece work, bonus, or subcontract arrangement; for example, the best locomotive-crane operators, who were never assigned to the simpler work of unloading coke, pig iron, or sand, but were necessarily always used on jobs requiring greater experience and skill, such as servicing ships in dry dock and other work of a generally unmeasurable nature.

Apart from the strictly productive labor in the Department whose maximum output could not be encouraged by any of the usual forms of wage incentive, there remained the entire supervisory force none of whom had an opportunity for increasing their earnings by increasing their efficiency though exercising at a near maximum.

The plan which was finally evolved for this first department of the general and service group and which was intended to place the entire department on a measured cost-efficiency basis is described in detail below.

As the basis on which the group plan was designed was one of increasing cost efficiency, an "expense-budget normal" was first set up after a careful study of past costs in this department as compared with the total yard direct payroll for equal periods. In order not to handicap the participating group at the outset, the budget normal upon which the bonus plan was based did not

exact any immediate betterment in costs over past performance before the zero or starting point of bonus earnings could be reached. The budget normal which was set up as a performance level to be beaten in order to pay a bonus is shown in Fig. 3 as expense-budget normal *A*. This chart also shows very clearly the results obtained in the way of cost improvements in this department since inaugurating the group plan.

Details of Bonus Plan

The following joint memorandum authorizing the installation of the group bonus plan was issued to those concerned by the Time-Study Engineer, Foremen of Transportation Department, and Assistant Superintendent of Material Control, covering the details of the Bonus Plan:

AUTHORIZATION INSTALLATION OF BONUS PLAN

Joint Memorandum, March 1, 1928

Newport News Shipbuilding and Dry Dock Company

Transportation Department—054

Subject.—Bonus plan for employees of the Transportation Department based on monthly savings made between cost and the expense budget.

Budget.—The monthly budget used in the bonus plan will consist of a standby charge of $5000 plus 2.34 per cent of grand total direct labor for the yard. To this will be added an amount equal to all expense in account 4.

Cost.—Cost in this department to be compared with the above budget will consist of all expenditures under expense accounts 1 to 9, inclusive, as shown in the Blue Cost Book, all departmental cost or labor charged directly against a particular contract or order number, all plant service charges, and all departmental bonus payments which will be charged to 0544–4.

Plan.—All employees of the Transportation Department, including the foreman, are to share in 50 per cent of the total savings of departmental budget from month to month based on a rolling average of six months.

Bonus Division.—The department shall be divided into the four following classes for the purpose of proper bonus divisions: Class 1, foreman; class 2, chief dispatcher; class 3, dispatcher and clerk; class 4, all other employees. Each class shall receive a certain percentage of the bonus to be divided, and this percentage will be governed by average number of men in department from month to month. Classes having more than one man will have respective bonus divided pro rata among the men of that class according to hourly rate and number of hours worked during the month.

Bonus Distribution by Per Cent Among Classes.—

Total number of men in department, inclusive	Classes 1	2	3	4
86 to 95	3.3	2.2	2.0	92.5
96 to 105	3.0	2.0	1.8	93.2
106 to 115	2.7	1.8	1.6	93.9
116 to 125	2.4	1.6	1.4	94.6
Over 125	2.1	1.4	1.2	95.3

Notes.—In case material changes are made in the organization of the work from time to time (other than variations in number of employees), the percentage of bonus division for the several classes will be equitably adjusted to suit the new conditions. Any bonus systems of piece-work prices now in operation will become void the date this plan goes into effect. It is proposed to put this plan in effect March 1, 1928, and it will be subject to revision January 1, 1929.

Determining Basis for Bonuses

In setting up a bonus plan of this type it has been found that there are certain steps to be followed. First, the functions of the department are to be analyzed with the idea of determining where service is rendered and how it is to be gaged. The plan usually embraces the whole department, but may be used for certain groups of persons in one or more departments. In the case of whole departments, service is usually rendered either to the whole plant or to certain other departments. The amount of service to be required is determined by the number of persons to be served or the pay of these persons. For some plans there is used the total payroll of the departments served and for other plans the total direct-labor payroll, depending on the type of service required of the department to be placed on bonus. Some departments serve not only the productive or direct labor of other departments, but the indirect labor as well, while in other departments service is rendered only the productive labor.

After deciding where and how service is rendered and how it shall be gaged, the next step is getting the figures, which are to be in two groups, the gross budget figures and the cost figures. The gross budget figures are those on which the budget is to be based and are those already explained—namely, number of persons served, total pay of those persons, or total direct labor of the departments served. The cost figures are to include all costs of the department to be placed on bonus, no matter how these costs are incurred, exclusive of direct material.

These figures are to be taken by months over a period of time extending from peak to slump, or vice versa, if possible. This gives the two extremes in departmental cost and serves to make the budget plan more accurate.

A graph is then plotted with the cost figures, and those from which the budget is to be set, parallel to each other so as to show the amount of divergence between the two extremes, high and

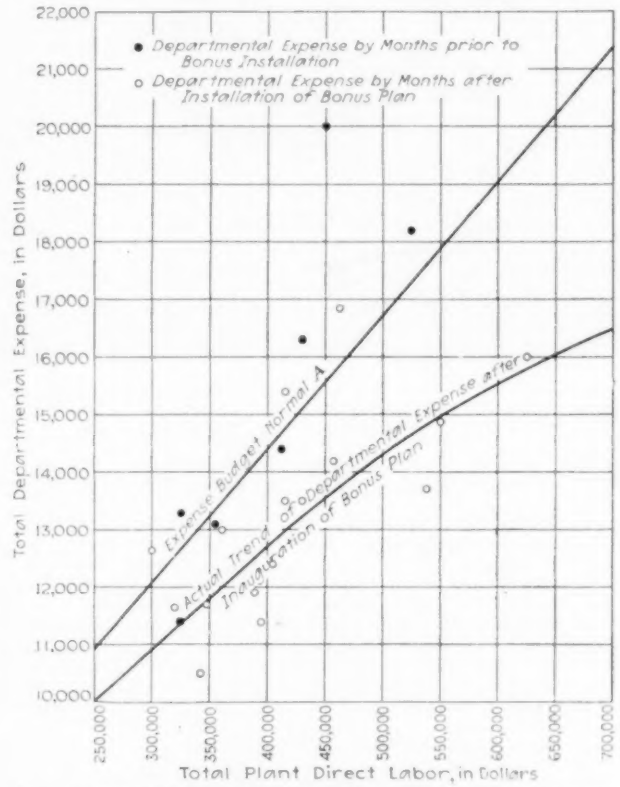

Fig. 3 Chart Showing Effect of Group Bonus Plan on Costs of Transportation Department

low. In arriving at a budget there is first set a constant, or standby, figure. This is supposed to be the cost of the department at a mythical zero of work in the plant. The larger the constant figure, the smaller the amount of fluctuation in the budget, and vice versa. However, this constant should in no case be larger than 75 per cent of the department's smallest monthly costs. Next there is the item of special allowances to be taken care of. In the plant under discussion the departments have very little to say as to the amount of money to be spent in repairs to the buildings used by them, this being taken care of by the Plant Engineer, so an allowance is made to take care of account 4, which is repairs to buildings and structures (and a part of the departmental expense). Other special and periodic charges are to be taken care of by allowances.

In setting the budget the cost figures are used for the six months immediately preceding the installation of the bonus plan. There is subtracted from the total six months' cost the standby charge for the same period and the total of the items for which allowance is to be made. This gives what might be

termed "net cost." Then the percentage of net cost to gross budget figures for the same period is determined. This gives the standby, plus allowances, plus a percentage of the gross budget, which is to be the departmental budget. If the divergence between cost and the gross budget as plotted on the graph is too great, it can be taken care of by following the foregoing procedure for the six months at the peak (or slump) and plotting the results on a graph. Connecting these two points by a straight line gives the intermediate budget.

The final written plan should not only give in concise form the foregoing results, but should also state which employees are to participate in the bonus and to what extent they participate. It is well to include in the plan a statement as to the quality of service rendered not being impaired or the plan is void. This is for the purpose of preventing a reduction of cost by lowering the standard of the service. This is passed on by a committee when necessary.

Finally, the plan carries a date when it is to become subject to revision. The revision dates are usually January 1 and July 1. The plan is practically guaranteed until then.

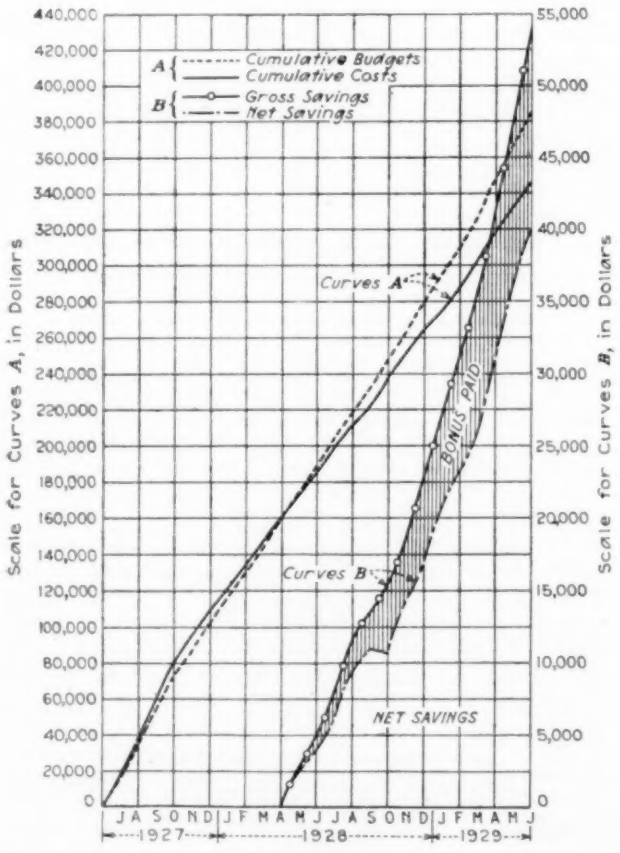

Fig. 4 Effect of Group Bonus Plan on Costs of Transportation Department

After the plan is written it is agreed to by the responsible head of the department and by the head of the Time-Study Department, who is responsible to the management for formulating and operating the various plans.

Cost Results From Bonus Plans

Fig. 4 shows graphically the effect of the Transportation Department's group bonus plan, as described, on the operating costs of that department. In the same way Fig. 5 indicates the results obtained in all of the general and service departments now working under similar group-participating bonus plans.

The plan is set up on a six months' rolling average; that is, it was started with six months' cost and six months' total yard direct payroll, and as a month is added a month is dropped—when April, 1929, is added October, 1928, is dropped.

Table 1 shows the form used for bonus computations for the

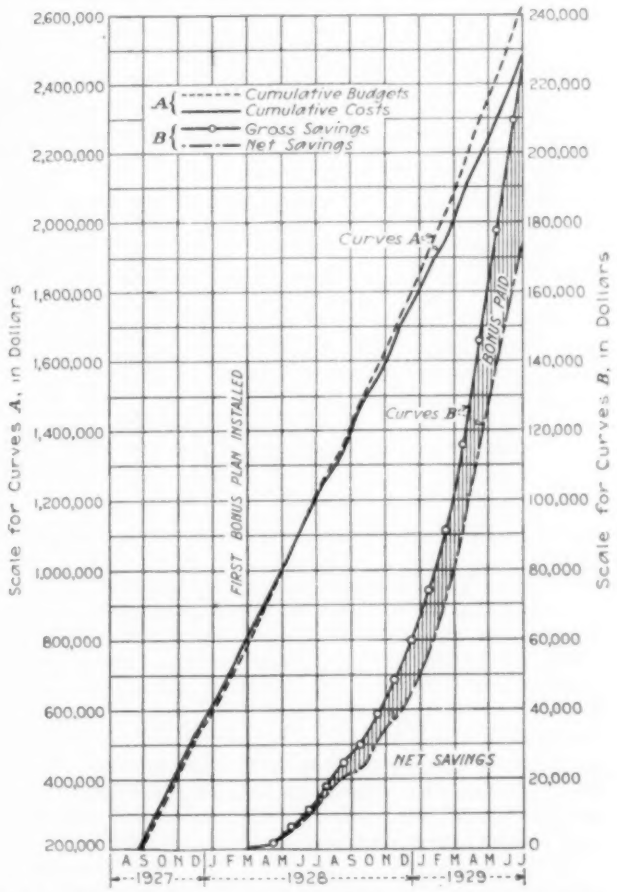

Fig. 5 Effect of Group Bonus Plan on Costs of General and Service Departments

Transportation Department. Similar records are kept for all service departments.

As stated elsewhere, in the bonus plan the savings shown between the budget and cost are split evenly; one-half of the savings is paid to the men in the department, as outlined in the bonus plan, and the other half goes to the company. At the end of a month, when the bonus is paid, the amount paid is charged into the next month's cost for the department, so that in the course of time it figures out less than an even division, as shown in Figs. 4 and 5.

All of the costs of the department are kept; that is, the total payroll plus all charges for repairs to equipment, coal, oil, waste, office supplies, etc. As will be seen, this gives every one a chance to effect a saving all down the line, not only in the number of men on the job and the length of time on each job, but also in the quantity of coal consumed and other features. This coal is quite an item with the present equipment.

The biggest factor in getting this plan over is "selling" it to the men in the department. This takes a lot of time and salesmanship, and for the first two departments there was put on this plan one man who lived right with them for the first two months,

and it was his job to suggest every saving possible to the foreman. Naturally the first people to see the benefit of the plan are the supervisors, and once they are convinced, the conversion of the others is easy.

As is seen from Table 2, a slight decrease in the percentage of men in this department as against the total yard direct-labor force was shown in 1926. In January, 1927, a new supervisor was put in charge of this department, and he made a further reduction. In March, 1928, the bonus plan was started and still further improvements were shown, and the end is not yet in sight.

The actual bonus paid the men in this department for the month of May, 1929, was about 21 per cent of their wages, which is the largest bonus paid to date.

All of the service departments are now working on some kind of an incentive system.

[a] Deficit.

TABLE 2 AVERAGE NUMBER OF MEN IN ATTENDANCE IN YARD AND IN TRANSPORTATION DEPARTMENT

Year	Plant	Transportation Department	Percentage
1924	4228	127	3.0
1925	4664	141	3.0
1926	5400	142	2.6
1927	5256	110	2.1
1928	4403	84	1.9
1929 to end of May	5430	83	1.5

Storekeeping

Nearly every plant has a Storekeeping Department. The bonus plan in the Storekeeping Department was started in May, 1928. This plan was worked out from the number of men required in the storerooms to supply material to the mechanics and other production workers. As will be seen from Table 3, there were four years' figures to work from—1924, 1925, 1926, and 1927.

TABLE 3 AVERAGE NUMBER OF MEN IN ATTENDANCE IN PLANT AND IN STOREKEEPING DEPARTMENT

Year	Plant	Storekeeping Department	
1924	4228	91	1 storekeeper to every 46 employees
1925	4664	85	1 storekeeper to every 55 employees
1926	5400	104	1 storekeeper to every 52 employees
1927	5256	108	1 storekeeper to every 48 employees
1928	4403	74	1 storekeeper to every 59 employees
1929 up to June	5430	78	1 storekeeper to every 69 employees

A good comparison here is to take the year 1927, when there were no bonus plans in this department and there were 5256 employees in the whole plant and 108 men in the Storekeeping Department, or 1 storekeeper to every 48 employees. Compare this with 1929, when there were 5430 total employees, with 78 men in the Storekeeping Department, or 1 storekeeper to every 69 employees—a reduction of 30 men in the Storekeeping Department, with approximately the same number of employees in the yard.

The following is the bonus plan as adopted for this department:

STOREKEEPING DEPARTMENT BONUS PLAN

Joint Memorandum, May 28, 1928

NEWPORT NEWS SHIPBUILDING AND DRY DOCK COMPANY

Storekeeping Department—053

Subject.—Bonus plan for employees of the Storekeeping Department based on monthly savings between cost and the expense budget.

Budget.—For a four-week month the budget will consist of a standby charge of $2000, plus $1.72 for each man in attendance throughout the yard, and to this will be added an amount equal to all expense in account 4, repairs to buildings and structures. For a five-week month the budget will consist of $2000, plus $1.903 for each man in attendance throughout the year, and to this will be added an amount equal to all expense in account 4, repairs to buildings and structures.

Cost.—Cost in this department to be compared with the above budget will consist of all expenditures under expense accounts 1 to 8, inclusive, as shown in the Blue Cost Book. All departmental cost or labor charged against a particular contract or order number and all departmental bonus payments will be charged to 0532–4.

Plan.—(1) All employees of the Storekeeping Department, including the foreman, are to share in 50 per cent of the total savings under the budget from month to month, based on a rolling average of six months. (2) This is providing the service of the Storekeeping Department to the operating departments is not impaired. (3) The department budget and the provision in (2) as to the service to operating departments not being impaired will be determined jointly by a committee of three, composed of General Manager, Production Manager, and Production Engineer. This committee will also determine the amounts of bonuses earned.

Bonus Division.—Bonus paid each individual will be paid according to the total amount of money each individual receives as salary or wages during the month.

Notes.—In case material changes are made in the organization of the work from time to time (other than variations in number of employees), the plan will be equitably adjusted to suit the new conditions. Any bonus system or piece-work prices pertaining to or affecting the Storekeeping Department will automatically become void the date this plan takes effect.

Effective May 29, 1928; subject to revision, January 1, 1929.

(Approved) _____
Material Agent

(Approved) _____
Time Study Engineer

Since the first of this year up to May, inclusive, this plan has paid the employees of the Storekeeping Department a bonus as follows: January, 5.6 per cent; February, 5.2 per cent; March, 5.2 per cent; April, 5.2 per cent; May, 6.9 per cent.

The total cost of operating the Storekeeping Department for the year 1927 was $144,185 for 5256 employees. If this is compared with a total cost of $52,523 for the first six months of 1929, it will be seen that there was a saving of about $39,000 for this year in this one department.

It is believed that this saving is due largely to the bonus plan now in effect, and each one of these plans is showing equally good results.

The general bonus plan used for most of the other service departments is similar to that given for the Transportation Department, namely, an equal division or "split" of the "savings under department budget." This system corresponds to the Halsey premium system of wage incentive. This seemed the simplest and most desirable plan to use with such a large number of variable factors entering into the budget estimates.

TABLE 4 BUDGET DETERMINANTS FOR GENERAL AND SERVICE DEPARTMENTS GROUP BONUS PLANS

Symbol	Department	Approximate employees	Budget determinants K	$+$	Pn
015....	Cashier's office	15	$3000		18.5c. per employee in attendance
016....	Accounting and cost	29	3000		56.0c. per employee in attendance
017....	Timekeeping	78	3000		1.95% yard payroll
018....	Tabulating	23	800		$8.80 per 1000 cards
021....	Employment	10	500		0.29% yard direct labor
026....	Janitors	18	900		58c. per operative employee
029....	Watchmen	50	3000		0.89% shipwork labor only
030....	Machinery drawing room	26	2000		10% payroll of department
....[a]	Hull drawing room	11	400		3% payroll of department
037....	Correspondence	25	500		6% payroll 030 Division
041....	Plant engineers	25	3000		0.48% yard direct labor
052....	Material department office	52	4000		$1.01 yard employees in attendance
053....	Storekeepers	80	2000		$1.72 yard employees in attendance
054....	Transportation	83	8000		1.38% yard direct labor
055....	Drayage	27	800		0.96% yard direct labor
056....	Lumber storage	28	..		$3.07 per 1000 bd. ft.
058....	Steel stock storage	19	1250		40c. per ton of steel
060....	Production division	88	8000		85% yard direct labor
066....	Time study	34	A 1600		1.02% yard direct labor
			B ..		0.25% net gain on all operative department direct labor budgets
067....	Order	18	..		11.2c. per sq. yd. blueprints issued
	Total participating employees	739			

[a] Employees participating in machinery and hull-drawing-room group bonus plans do not include draftsmen. All drafting is done on a subcontract or piece-work basis.

Budget Formula: Up to "normal" output, budget B equals a "standby cost," constant K, plus variable expense which varies with the volume of work or service rendered Pn. That is, $B = K + Pn$.

Note.—Actual figures are given in many cases.

Rolling Average

The six months' rolling average is used because the monthly fluctuations in the actual cost figures for departmental expenses are naturally apt to be very great for service departments; in other words, a longer period than one month for averaging purposes enables each department to make some bonus earnings each and every month if the average costs for the previous six months are satisfactory. If there was used a one-month period only, there would be some months where no bonus money was earned and other months where the earnings would appear excessive. To put it another way, the six months' rolling average is really more nearly correct as a matter of costing, for the reason that many seasonal or abnormal charges, such as heavy repairs to equipment or other things of a temporary or unusual nature, may cause charges to fall in the cost records of one month which really are incident to several previous months.

Budget Formula

The general formula given in Table 4 for a budget (namely, $B = K + Pn$) is universal up to "normal output," and from Table 4 it will be seen that there are several different uses or meanings of P and n in various departments, expressed in words as follows:

Method	P	n
(1)	Standard or budget cost per unit n	Number of units measured; as, (*a*) prints issued; (*b*) 1000 bd. ft.; (*c*) tons of steel handled; (*d*) cards punched.
(2)	Cents per unit n	Number of employees in attendance in operative departments.
(3)	Cents per unit n	Number of employees in attendance in yard (whole plant).
(4)	Per cent of n	Dollars payroll of the service department (includes direct and indirect labor).
(5)	Per cent of n	Dollars payroll of the division to which service department belongs.
(6)	Per cent of n	Dollars direct labor of division.
(7)	Per cent of n	Dollars payroll of yard.
(8)	Per cent of n	Dollars direct labor of yard.

Organization and Functions

Since the management and operation of service departments embrace the whole field of management, of which a wage-incentive plan is only a part, although a very important part, as outlined, consideration should be given in more detail to the other factors of management if space permitted. Some features, however, will be mentioned. Real management of any plant or department in a plant naturally begins with organizing and defining clearly the functions or duties of each department; then comes the further assignment of duties to each individual in the department. Printed booklets or manuals have been prepared and issued for this purpose in the plant under discussion. These are educational and instructive to all concerned and of great aid in training executives and other employees. Further intensive and special training all along the line is of course the next step in the same direction. Proper relationships between departments, with coordination of effort without duplication or friction, is one of the great problems of management in a large plant such as has been described.

What Is Expected of Service Departments

The bonus plans described are mainly based upon a good financial showing by the service department itself; that is, the department should render service at the lowest practicable cost, provided that the service itself is not impaired. Quality of service is most important of all—whether engineering and design, storekeeping or accounting, or other service to the operative departments. The promptness and the reliability of service are also of the greatest importance. All service work should be planned and scheduled in detail, so far as practicable. The three main elements of good service, then, are (1) quality, (2) time, and (3) service cost. The measure of the result or effect of good service is the value rendered to, or benefit received by, the departments served. This usually shows up in reduced costs of direct labor and materials.

In the plant discussed there has been a reduction in direct labor costs on large high-grade passenger ships (such as the *Virginia* and *Pennsylvania*) of about 30 per cent during the past six years.

Advantages and Disadvantages of Bonus Plans

Advantages

(1) Simplicity. Easy to understand. Easy to operate at low cost. One man handles all these bonus calculations.

(2) Interest Factor. Creates a real personal interest on the part of every employee in improved service at minimum costs. Employees watch for waste in their departments. Thinking ahead is stimulated.

(3) Financial. Fairly immediate financial gain to a company after the system is effective in any department. Employees start earning bonus money, taking a great interest, however small the bonus. Average earnings of all service employees over their usual pay are about 9 per cent at present. The more they earn, the more profits the company makes.

(4) Compared to other plans, such as "stockholding" for employees in general, the bonuses more nearly reward the various employees and groups in proportion to their value to the company.

Disadvantages

(1) Most of the disadvantages arise from the extreme difficulty of setting correctly the bogeys or budgets, which can hardly be avoided. The formula $B = K + Pn$ is not absolutely correct, even up to "normal" output, and at normal output or above the budget line should droop or flatten out. The net result, however, in bonus payments is not at all serious—largely because of the protection against poor estimates or standards by the even-split idea.

(2) The plan described may not be regarded by some as "scientific," and in the usual manufacturing plant it may be practicable to improve over the conditions described. The authors have both had several years' experience in various kinds of manufacturing, which leads them to this conclusion. Offsetting this criticism, however, it is felt that an "immediate sure saving" of over $200,000 a year is preferable to a postponed possible saving, after years of more scientific study, of perhaps a larger amount. In fact, the present plans make it easier to go further and more scientifically into the whole matter. In office management in particular there is room for still greater improvement. The present plans have created and maintained an interest by heads of departments in any possible improvements that may be suggested for their departments. The problem of management of "creating and maintaining" the proper interest is probably the most difficult thing in the world to accomplish. Custom, habit, tradition, vanity, and prejudice are five arch-enemies to progress.

An Opportunity

The main theme of this paper is that of offering an *opportunity to all employees* in a plant to increase their earnings by some definite scheme of extra reward for extra thinking and action and at the same time increase the company's net earnings. In the large plant discussed incentives were already in effect before service-department bonuses were started, with excellent results not only for productive- or direct-labor employees, but for practically all executives, major and minor, including foremen and gang bosses. The service-department employees are entitled to as much consideration as other employees, and the supposedly insurmountable difficulties of giving them this consideration have at last been overcome in a simple and practical manner.

Appendix No. 1

Duties of the Production Engineer

The Production Engineer is responsible to the Production Manager for the performance of the production staff duties briefly described under the following headings. The Production Engineer acts for the Production Manager in the absence of the latter.

061 *Cost Control*
- Expense and labor budgets by departments
- Critical comparisons of actual cost with budgets by departments
- Cost system development.

061 *Master Schedules*
- Master schedules, general planning and allocation of work
- Coordination of material control system with the master schedules
- Critical comparisons of actual progress with master schedules and expediting work as required to meet delivery dates
- Reports for progress payments.

062 *Estimating*
- Cost estimates for all work except for ship repair and plant work
- General review of ship-repair estimates amounting to $10,000 and upward
- Determination of the desirability of work to suit production facilities
- Delivery dates for all proposed work
- Job orders for all work except for ship repair and plant work.

063 *Testing Laboratory*
- For duties of this department see separate heading in this section.

064 *Locomotive Engineering*
- Inspection records for locomotive repairs
- Orders and material records for new material required
- Miscellaneous railroad orders
- Progress reports for locomotive repair work.

065 *Inspection Department*
- For duties of this department see Section I.

066 *Time-Study Office*
- For duties of this department see separate heading in this section.

067 *Order Department*
- For duties of this department see separate heading in this section.

068 *Welding Research Department*
- Development and extension of welding and cutting to all classes of structural work, and cooperation with the design, sales, and operative departments to this end
- Welding and cutting research and tests
- Recommendations on mechanical methods and on the design and purchase of equipment and supplies for welding and cutting
- Standardization of welding and cutting practice
- Supervision of training and certification of welders.

Note.—The Assistant Production Engineer will exercise such supervisory duties in the above list as are assigned to him by the Production Engineer.

Duties of the Testing Laboratory

This department is a testing service station for the Yard and is under the immediate charge of the Metallurgist who reports to the Production Engineer. The work of this department consists of making determinations of the chemical and physical properties of purchased materials that may require analysis, control of the characteristics of outgoing materials to specified requirements, and such technical and research service as may be rendered for the improvement of materials and the regulation of processes as mixing, melting, and heat treating, all for the general purpose of obtaining better products at lower costs.

This work, including the necessary compilations of data and reports, is carried on under several headings which may be given briefly as follows:

1 *Chemical*
- Control of foundry analyses for iron, steel, brass, bronze, and other metals
- Testing of incoming materials and outgoing products.

2 *Metallurgical*
- Metallurgical research and investigations
- Development of specifications and standard practice instructions
- Heat treating control
- Microscopic examinations.

3 *Physical*
- Preparation of test specimens
- Testing operations as pulling, compressing, bending.

4 *Fuels and Lubricants*
- Comparative analyses of fuels as coal, coke, fuel oil, and gases; lubricants as oils, greases, and compounds.

5 *Paints and Varnishes*
- Comparative analyses of ingredient materials and developing, formulating and testing of paints, varnishes, and lacquers.

6 *Research*
- Investigations of troubles in established processes
- Development of improved methods or materials.

Inspection System

1 *Date in Effect.*—The following inspection system has been agreed on after consultation with the superintendents and material agent, and is to be followed from August 1, 1927. Departures from this system are not to be made without consulting the Production Manager or Production Engineer.

2 *Purpose.*—To maintain the company's reputation for good workmanship, to keep incoming material up to specifications, to avoid delays and reduce the cost of correction by detecting errors before material has been worked into the final assembly or shipped to the purchaser.

3 *Scope.*—Inspection shall cover incoming material, workmanship, conformity to drawings, specifications and orders, and the general suitability of the material or part for the service intended.

4 *Process Inspectors.*—Detail inspection of work in process will be made by inspectors who will report directly to the division superintendent. In the larger shops this work may be divided among several men but in the smaller shops may be handled by one man. These inspectors will devote a part of their time only to inspection, as they will also check detail progress and quantity and in some cases do piece-work counting.

5 *Product Inspectors.*—In addition to the process inspectors there will also be a group of product inspectors, reporting to the Production Engineer, who will make final inspection of all finished or partially finished material to be delivered by one division to another, or to a warehouse, ship, or outside purchaser. Each product inspector will keep informed as to the general progress of work in his territory so that he may be able to give information relative to delivery dates.

6 *Duties of Inspectors.*—Process inspectors will pass on work in process with the idea of eliminating or correcting defective material or improper workmanship in the stages before the parts reach the product inspector. They will consult with the product inspectors relative to the suitability of material for a job in case defects or errors are discovered and will arrange for replacing all condemned material. Particular attention will be given to correct heat numbers and piece marks, or other identification marks. Process inspectors will also be responsible for the correct dimensions of all parts machined to fit other work which is not readily available for checking by the product inspector, such as stern tubes, bushings, cylinder liners for repair jobs, etc. Product inspectors will pass chiefly on the general quality of work, its adaptability to the service for which it is intended, the correctness of dimensions affecting final assembly after leaving the shop (except as noted above) and the agreement with the requirements of the U. S. Steamboat Inspection Service, the Classification Societies, or other inspection agencies. They will arrange for the presence of purchasers' representatives or the representatives of inspection agencies on all tests or inspections on which their approval is required. They will pass on all corrections of major errors in shop work and the reclaiming of defective castings and forgings and will see that the approval of the owners is obtained if required. They will consult freely with the superintendents and the drawing room heads to insure corrective work being done in the best possible manner, and will pass on to the drawing rooms, through the Production Engineer, suggestions for improvements in design discovered in inspection. They will also observe work in process, particularly on large parts, wherever preliminary inspection of this nature will facilitate final inspection and avoid setting up the work again. Product inspectors will also supervise the loading for shipment of all material requiring special cars, or special blocking or packing.

7 *Inspector's Decision.*—In case of doubt as to interpretation of drawings, orders, specifications, or other requirements, the decision of the Chief Inspector will govern, subject to appeal to the Production Engineer whose decision will be final.

8 *Drawings and Orders.*—When necessary the product inspectors will be provided with copies of the shop orders, specifications, and drawings, but wherever it can be done without hindrance to the shop work, they will have access to the shops' files or drawings and orders, to avoid duplication.

9 *Reports.*—Process inspectors will make reports as may be required by their superintendents. On all material to be shipped away the product inspectors will submit promptly to the Material Department a detailed inspection report listing each piece, or group of pieces, to be shipped. The Chief Inspector will report daily to the Production Engineer on all major inspections, tests, and corrections.

10 *Organization of Product Inspection System.*—One Chief Inspector to whom all product inspectors will report. The Chief Inspector will cover special jobs and make such reports and investigations as may be required by the Production Engineer. One inspector for the main machine shop, brass machine shop, and erecting machine shop to inspect valves, manifolds, pipe castings, and all other fittings made for steam, water, and fuel oil pipe lines. One inspector for all other work of the main machine shop, brass machine shop, erecting machine shop, and for all work of the boiler shop. One inspector for the foundry. One inspector for the blacksmith shop, forge shop, and the H. F. and P. group. One inspector for the north side structural shop and hull assembly division for work to be shipped to outside purchasers. Additional inspectors and other duties will be added as conditions may require.

11 *Physical and Chemical Inspection.*—All physical and chemical tests will be in charge of the metallurgist whose duties are described under testing laboratory in Section III addenda.

12 *Inspection of Incoming Material.*—The material agent will arrange for the inspection of all incoming material. This inspection will cover quantity, quality, conformity to purchase specifications, and condition on receipt of shipment. An inspector, qualified by experience for the work, will be designated by the material agent to inspect all incoming steel except where the material agent is satisfied that thorough mill inspection has already covered the ground. Lumber and other bulk material will be handled in the same manner. In all inspection of an engineering or special nature such as large castings, machinery, special fitting, or equipment, the material agent will call on the Production Engineer for technical assistance and the Production Engineer will, if necessary, consult the drawing room ordering the material. The same procedure will be followed in case important material is received of questionable quality or in damaged condition necessitating corrective work in the yard. Each case in which inspection shows the purchase specifications to be incomplete or faulty will be reported to the Production Engineer in order that satisfactory specifications may be given on future purchases.

Duties of the Time-Study Department

1 Make time studies and collect data on all classes of work
2 Get this data in such shape that it can be used for estimating and for establishing piece-work prices
3 Establish units of measurement for all classes of work
4 Suggest improvements in methods, tools, fixtures, and equipment wherever possible to increase production
5 Promote the cooperation of the workers with the incentive systems
6 Furnish the superintendents, assistant superintendents, or foremen with any data they may require which we have, or can collect
7 Establish piece-work prices in conjunction with Foremen
8 Write all piece-work price tickets
9 Prepare uniform working of piece-work tickets for the respective classes of work to be done
10 All piece-work prices to be set before the work begins
11 Check totals of piece-work prices with labor budgets
12 See that approved piece-work prices are not increased or decreased, except for increase or decrease in work. When prices are increased or decreased, a statement in writing, covering in detail the reasons therefor, must be submitted and agreed upon
13 Furnish any data required by the Production Engineer for estimating purposes
14 It is to be understood that no piece-work price is to be put into effect until approved and signed by foreman of department or some one whom he may designate, and by some one in the Time Study Department.

Duties of the Order Department

The principal work of this department has its beginning in the receipt of plans from the several drafting offices in which they are made. This work consists of taking from the plans or bills of material all items to be manufactured and issuing production orders for them to the departments to do the work; making out and issuing identification tags to accompany each part through its interdepartmental routing; making from the plans and issuing the necessary blueprints to the shops and departments to do the work called for.

This work, and certain other duties carried on by this department, are more particularly described under the following headings:

1 *Production-Order Section.*—It is the duty of this section to write the production orders from the plans or other sources of design authority and to indicate on the orders the interdepartmental routing for each item from its source to destination; to make out the tags to accompany and identify each item; to apply the routing to the material control record sheets; and to make out the distribution lists for blueprints for the departments doing the work, superintendents offices and others concerned. It is provided in the routine of this work that the distribution to departments of copies of the production orders and blueprints, material-control record sheets, and the route of the identification tags shall agree with the routing shown on the production orders. In connection with the duties of this section it may be noted that certain classes of work, as built-in structural work, do not require detailed routing on the production orders. For this class of work the same care is exercised in making out the distribution lists for blueprints for all concerned as for work going through the manufacturing departments. Certain miscellaneous duties are performed by this department as it affords a convenient center in which they may be handled; as, catalog of material stores symbols for inventory purposes, catalog of drop forgings and balance-of-stores work for this class of material, summaries of weights placed on board ships and similar weight summaries as needed, multigraph work.

2 *The Blueprint Section.*—This operates all blueprint-room equipment, makes and delivers the blueprints and other reproductions as called for by the print lists and keeps suitable records to verify their distribution. This section also clears back to the files the tracings and other original sheets after the prints have been made.

3 *Weight Office.*—The work of this office consists principally of weighing, or compiling weights from authentic sources, of designated groups of material placed on board ships and reporting these weights to the Estimating Department. Similar weight reports will be made for certain classes of hydraulic work and other products as required.

Duties of the Employment Manager

The employment manager is responsible to the management for the supply and training of suitable labor and for the promotion of harmonious industrial relations. This work is organized under several headings which may be given briefly as follows:

1 *Employment Office*
- Correspondence
- Interviews
- Placements
- Ratings
- Transfers
- Re-ratings and promotions
- Furloughs
- Terminations

2 *Employment Records*
- Service
- Occupational
- Attendance
- Earnings
- Turnover by departments

3 *Employment Service Information*
- Addresses
- References
- Board and lodging
- Houses and apartments
- Miscellaneous service work

4 *Training*
- Apprentice school
- Job training

5 *Industrial Relations*
- Employees' representation plan
- Safety committees
- Plant publications
- Other activities.

Duties of the Plant Engineer

The Plant Engineer is responsible to the management for providing suitable buildings and equipment for carrying on the productive work of the plant in an economical and expeditious manner. It is his duty to advise with the various department heads and investigate any requests for new equipment or buildings, changes in locations of present equipment or alterations in the design to increase efficiency, and to design any needed special equipment which cannot be obtained from the usual sources. This work is organized under the following headings:

1 Office Staff
2 Buildings and Structures Section
3 Machinery-Design Section
4 Small-Tools Section
5 Electrical Section

1 *The Office Staff* in addition to other duties keeps records by numbers and locations of all numbered machines and other equipment throughout the various departments. This section also takes the monthly readings of all meters measuring electric current, gas, and water purchased and of such other meters as are installed to record the electric current, gas, water, and steam used in various parts of the works.

2 *The Buildings and Structures Section* is in charge of a structural designer who is capable of designing buildings, cranes, crane runways, etc., and of advising the overload load carrying capacity, if any, of any bridge crane, jib crane, or building structure in the yard. Also, in this section there is a building inspector whose duty it is to inspect all buildings, estimate the cost of repairs or proposed changes in the arrangement of buildings or their equipment and to see that repairs and changes are carried out in a satisfactory and workmanlike manner.

3 *The Machinery-Design Section* is in charge of a machinery designer who is capable of designing special equipment and advising as to the overload capacity of existing equipment. This section also has charge of the design of special tools, jigs, and fixtures required for unusual jobs.

4 *The Small-Tools Section* is in charge of a small-tools inspector who has charge of the inventory of small tools, the interdepartmental transfer of small tools, tests, and standardization of small tools. This inspector's duties also include the inspection of all requisitions for small tools to be sure that only those that are standard will be ordered.

5 *The Electrical Section* is in charge of a designer who is capable of designing, laying out and ordering switchboards, control equipment, and motors, and of determining wire sizes, etc., for power transmission.

Emergency machinery repairs amounting to $50 or less are taken care of by the repair department directly, all charge being made directly against the machine number. For major repairs or general overhauls the work is covered by a foreman's repair order which is submitted to the Plant Engineer who issues a repair job order covering the work. In this way the charges are segregated so that in some cases, when so authorized, the departmental budgets may be relieved of unusual special expenses for which they cannot be held strictly responsible.

Upon requests from department heads the Plant Engineer issues all special equipment orders to cover machines, tools, jigs, and fixtures which are purchased or manufactured to execute particular jobs or contracts. Upon completion of the work these special equipment orders are closed and final returns are available for the inspection of those interested.

The Plant Engineer shall also be responsible for all costs for new small tools charged in asset account 6 and for the quantities of such tools acquired either by purchase or by being manufactured in the yard.

Discussion

Felix W. Zuelow.[3] In many cases, the company with which the writer is connected has established variable budget standards

[3] General Electric Company, Schenectady, N. Y.

on service labor for direct operative departments, applied to accurately time-studied productive operations; while in the case of general service departments, the several functions performed are carefully analyzed, and task standards established on all major controlling factors involved.

Obviously no real objection can be made to the point that it is preferable to secure an "immediate sure saving" by the methods described in this paper, rather than await more certain and possibly larger savings based on years of more scientific study, until a point is reached when there is a reasonable cause for doubt whether real savings are being effected under such procedure. While it is perhaps easier to go further and more scientifically into this whole matter of applying incentive plans to service departments, after comparatively rough, overall standards of performance have been tentatively established and tested out, nevertheless, it cannot be over-emphasized that such further and more scientific study into this subject is imperative, if satisfactory and permanent improvements along these lines are to be properly guaranteed for the future.

PAUL HECHT.[4] The very clear and detailed exposition of the subject of budgeting and wage incentives for service departments, as set forth in the paper, rather restricts the field for discussion, especially by one who is as sympathetic with the subject under consideration as is the writer.

The Newport News plan offers incentive payment to all employees of the service departments and is, therefore, more comprehensive than the plan at present followed at the South Philadelphia Works of the Westinghouse Electric & Manufacturing Company (hereinafter referred to as South Philadelphia), which offers incentive payment only to the department heads, superintendents, and foremen as the case may be, and to certain keymen within the departments who are able to influence and to exercise some control over expense. Furthermore, at South Philadelphia the incentive plan is not confined to those departments which Messrs. Ferguson and Blair classify as service departments, but applies also to the supervisors and foremen of the so-called productive or operating departments. Plans are being developed toward putting the rank and file of the service departments on an individual incentive basis so that work in excess of a measured standard, on which the regular wage or salary is based, will be compensated for by an increased wage allowance.

The difficulty of setting up a proper "expense budget normal" can be appreciated only by those who have had to attempt such a set-up under conditions prevailing in the Newport News plant and at South Philadelphia. As at Newport News, so at South Philadelphia, practically none of the work is duplicate work or of a repetitive nature. While the work at South Philadelphia is not seasonable to the extent prevailing at Newport News, there are such wide fluctuations in volume that on a theoretical basis the operating force in the plant could be varied from one to five or often six times a year.

Past records of performance intelligently scrutinized are, of course, the only means of determining a standard expense budget. The detail of setting up this standard differs in some respects at South Philadelphia from the method followed at Newport News. At Newport News, the normal budget upon which the bonus plan was based did not exact any immediate betterment in costs over past performance before the zero or starting point of bonus earnings could be reached. While such a method would be equitable if all of the participating departments were operating at equal efficiency before incentives were established, it is unfortunately a fact that such a condition does not exist in the average plant made up of many departments and thousands of employees. It is conceivable, therefore, that supervisors who have been conducting the operations of their departments with a high degree of efficiency from an expense standpoint would have greater difficulty in making a showing than would those who had been less energetic in expense control, and as a consequence those supervisors who put forth super-effort before incentives were introduced might suffer in bonus payment after incentive measures were applied as against those who had not exerted such extra effort. This is manifestly unfair. At South Philadelphia, therefore, while past performance over a period of several years was taken as a basis, practically all expense accounts were modified before bonus earnings could begin. This review was made jointly by the supervisor of the particular department involved and those members of the executive staff who were generally familiar with the operations of the plant as a whole. Some of the expense items were increased, and others decreased, and when the different departmental budgets were finally approved, they stood at figures ranging from slightly higher than recent past performance to reductions as great as 20 per cent below such performance.

In this connection it should be pointed out that the South Philadelphia plan provides that if a deficit is incurred in any department during any month, such deficit must be made up in succeeding months before bonus payments will be made. In order to avoid an undue hardship on those departments whose budgets had been reduced, a four months' moratorium was allowed when the plan was introduced. Under this moratorium each department was allowed a period of four months in which to reduce its expenses to the budget level. Any deficit incurred during these four months was not charged up against the department as an amount to be recovered or made up in succeeding months before bonus payment would begin. The Newport News plan apparently makes no provision for a penalty in case of a fall-down.

Another point of difference is that the standard expense allowance at Newport News is determined by either the total labor cost of the department or the total direct-labor payroll. This was considered at South Philadelphia, but owing to the wide volume fluctuations previously referred to, making it necessary at times to conduct from 35 to 40 per cent of the operations on an overtime basis, with its attendant overtime bonus, it was felt that labor earnings would not provide a proper standard and, therefore, productive hours were set up as the determining base. This procedure likewise controls any tendency that might develop in the occasional instance for the supervisor to build up his payroll dollars by working overtime when more careful planning might possibly avoid its necessity.

The South Philadelphia plan recognizes two kinds of expense, fixed and variable. Instead, however, of setting the fixed or standby figure at a mythical zero of work in any one department, which is practically impossible of determination, it was set at the more easily determinable point representing the normal operation of the department, and the factors were established for its modification within such ranges above or below normal as might reasonably be anticipated, say a year in advance. The normal or standard variable expense allowance divided by the normal or standard production hours gives the variable rate per hour.

Another variation from the Newport News plan at South Philadelphia is that the bonus is divided into two funds. Fifty per cent of the bonus, known as the departmental fund, is paid to the individual participants in cash provided there are no outstanding debits from former months, and the remaining 50 per cent is credited or debited, as the case may be, to an annual reserve fund, distribution of which is made once a year. All who participate in one fund also participate in the other, but

[4] Assistant to Vice-President, Westinghouse Electric & Manufacturing Company, South Philadelphia Works, Mem. A.S.M.E.

not necessarily to the same extent. Participation in the departmental fund is predicated upon the value of the service of the individual to that particular department, whereas participation in the annual reserve is predicated upon the potential contribution of the individual to the economical operation of the works as a whole, the theory being that no one department stands or falls by itself, and that there must be developed a spirit of cooperation among departments as well as among individuals, each helping the other to reduce its expenses to the economical limit and sharing in whatever benefit may be derived from such cooperative effort.

The results achieved thus far have been gratifying indeed. Costs have been decreased in innumerable ways and the earnings of employees have increased. An interest has been aroused in cost reduction which was not manifest before the incentive plan was introduced, and this interest will surely result in cumulative reductions in the years to come.

CARL E. JONES.[8] The "service departments" are outlined in this paper as including general office work, drafting work, accounting and cost departments, material supply, storage and transportation, time-study departments, and a great variety of other functions. The paper mentions also that the management of the service departments is complicated by the nonrepetitive character of the work, and also by the fact that practically all work is contract work, and by the further fact that the ship-repair business is somewhat of a seasonal business, with a large rush of work at various times and at other times this work is slack. There are eight specific points and two general aspects of the problem which the paper raises. The specific points follow:

1 One of the principal values which the speakers have claimed for their system is that it gives an opportunity for reward offered to those employees whose work cannot be definitely measured or standardized in the ordinary sense, who never before have had a real opportunity for increased earnings based upon their individual or group efforts and results.

The employees of the so-called service departments are thus placed under one heading by themselves, as opposed to the other workers whose number of units of work are theoretically more open to measurement. Whether the exact performance of each operator within many of the service departments cannot be measured more definitely and much better than previously has been attempted by most establishments is open to discussion.

For example, in several offices of large industrial plants the exact performance of each individual employee in the transcribing, correspondence, billing, accounts receivable, and certain other departments is measured and compared with predetermined standards which have been set. The pay of each employee, supervisors not included, is thus increased by whatever contribution in extra effort he or she has put in. The excess remuneration to the employee thus comes simply on the basis of individual performance, rather than as a portion of the saving made by the departmental group.

2 The paper mentions that group bonuses can be applied to the work of service departments where one cannot measure separately the output of individuals on account of the great variety of functions performed by nearly every person in these departments. Unquestionably there are many individuals in the service departments of all organizations whose work will not submit itself to any type of measurement. This should not make one close his eyes, however, to the fact that other employees are on jobs where time studies and fairly exact standards may be set. With the advent of machine methods for invoicing, keeping records of accounts payable, and accounts receivable, machine-bookkeeping for control, plant and costs ledgers, and the like, increasing opportunities are coming for determining the standard base pay and the extra pay due for extra exertion of each clerical employee.

In factory warehousing work, the installation of gravity conveyor systems has likewise tended to functionalize jobs, so that many of them are nearly as subject to time studies as are many so-called producing department jobs.

3 In order not to handicap the participating group at the outset, the budget normal upon which the bonus plan was based (according to the authors) did not exact any immediate betterment in costs over past performance before the zero or starting point of bonus earnings could be reached.

This point is very well taken. Whether the enterprise be one of ship-repairing, manufacturing, or retailing, the same fundamentals apply. If a group of employees, in order to make a bonus, had first to accomplish a certain amount of savings with no portion accruing to them, they would not consider the game worth while playing, and would not cooperate at all with the management in the installation of the plan.

4 The final written plan should not only give in concise form the results from the cost studies (according to the authors), but should state also which employees are to participate on the bonus and to what extent they participate. The plan generally includes a statement as to the quality of service rendered not being impaired or the plan is void. This is for the purpose of preventing a reduction of cost by lowering the standard of the service.

In this connection it is well to raise the subject of starting such a new procedure merely upon the initiative of the management versus starting such a system after the careful collaboration and cooperation between the management and the duly authorized representatives of the department or division affected. When the representatives of the employees go back to their fellow-workers with the plan as their scheme and preach it in that light, the proposed system has a certain backing it would fail to have if presented merely by the members of the management.

5 The subject just given has included a statement that the biggest factor in getting this plan over is "selling" it to the men in the department. This takes a lot of time and salesmanship, and for the first two departments that were put on this plan, one man lived right with them for the first two months, and it was his job to suggest every saving possible to the foremen.

Salesmanship and tact in suggesting savings would certainly be required during the early stages of any such plan. Once the initial suspicion and inertia of the employees were overcome, progress should be easier. If the management should place such an efficiency man in a department, it would probably be beneficial to introduce him as the helper of the employees in eliminating waste and thus getting extra pay, rather than to introduce him as the representative of the management while the system was started.

6 With all of the service departments now working on some kind of an incentive system, which means receiving extra pay, this thought comes to mind.

There is a constant urge, almost an ever-present necessity, for manufacturers and other enterprisers to reduce their costs. In the long run, many concerns have found this necessary in order to remain in the game. From one point of view, this incentive plan does reduce costs by the one-half of the saving kept by the company. There is the further thought, however, that if such a plan were to be adopted by manufacturers generally, and the other half of the saving were promised to the workers for time indefinitely ahead, trouble might arise some time in the future. Still greater competition might arise some day, the

[8] Dennison Mfg. Co., Framingham, Mass.

elimination or reduction of the group bonus plan for the service departments might be necessary for the preservation of the company, and still because the workers had come to think of this saving as their right, trouble might arise through any such elimination or reduction. This is mentioned merely as a possible eventuality.

7 The authors mentioned that a six months' rolling average, or moving average, is used because the monthly fluctuations in the actual cost figures for departmental expenses are naturally apt to be very great for service departments; a longer period than one month for averaging purposes enables each department to make some bonus earnings each and every month, and if the average costs for the previous six months are satisfactory.

This is undoubtedly very good procedure from the viewpoint of maintaining hearty interest in the plan upon the part of the employees. Nothing would be more discouraging to them, and more effective in breaking up the morale, than to be informed that they received no bonus for a given month simply because very expensive repairs had been charged into the costs that month. The use of a rolling average tends to remove the possibility of any such occurrence happening.

While a six months' moving average is probably quite satisfactory for a ship-repairing establishment, a twelve months' moving average would probably be more satisfactory in many manufacturing and retailing companies which are subject to marked seasonal fluctuations throughout the year.

8 One of the last points of the authors was that the service department employees are entitled to as much consideration as other employees, and the supposedly insurmountable difficulties of giving them this consideration have at last been overcome in a simple and practical manner.

This point is well taken. The percentage of service department employees to the remaining employees is sufficiently high in many concerns today, so that they should not obtain the idea that any discrimination is being made against them. If extra remuneration plans are in operation for producing department employees, it is certainly a strong point to have some such plans for the service department employees also. The difficulty of preparing incentive plans for service department employees should gradually be lessened as tasks tend to be standardized in many instances through the introduction of more machines into service department work.

The remaining two points deal with the topic in its broader phases, as follows:

1 Around 15 or 20 years ago, G. Charter Harrison began making us familiar with the system of cost accounting based around standard or predetermined costs, as opposed to actual costs. Once the standard costs were approved and put into operation, executive attention could be directed mainly into an observance of the deviations of the actual costs from the standard costs, rather than a study of the actual costs themselves. When budget figures in manufacturing departments first came on the scene, they tended to make a third figure; more recently, however, the budget has been woven into the cost accounting of the producing departments of some industrial concerns, and the budget figure and the standard or predetermined cost have become merged into one and the same figure.

During the last few years pioneer research work has been done in the realm of the supplementary or commercial and administrative costs of doing business within manufacturing companies. Detailed studies of the costs of given operations within the clerical, warehousing, and other service divisions of the enterprise have been made. It may be only a few years before standard costs are developed for these divisions, in many concerns; the given service department will then be charged with its actual cost and credited for its units of production at so much per unit; and its performance will be measured by the deviation from the predetermined cost or budget figure just like a producing department. Yet while this may not be possible for all service departments, it should still be considered as a desirable goal, for in so far as this can be done a budgeting and cost control over these divisions results.

2 Finally, with group-incentive plans of the type where one-half of the saving is given employees in their relationship to the profits of the entire company, the more a given department saves, the more will be the profit, or the less the loss, of the entire company, due to the saving of this one department. There may be years, however, when the profits for the entire company may be negligible or non-existent, even though the employees of a given service department might have made considerable savings and the employees of that department might still consider themselves entitled to their group bonuses. This raises the thought that possibly there might well be developed some possible interconnection between group incentive plans and the total company profits in the lean years. Perhaps this is not necessary or desirable in the case of this particular ship-repairing company, but it seems like a point which should be thoroughly considered before the adoption of such a plan by other concerns in either the manufacturing or mercantile fields.

P. L. Dildine.[6] It requires courage to criticize a successful proposition. This paper describes a wage-incentive method which has actually been applied to service departments with profitable results. It is to be presumed that the authors do not present this plan as being flawless. It accomplishes, however, the major purpose of which it was designed—namely, the reduction of costs. That is always worth while, provided the economies thus effected do not later react in greatly increased costs and loss of business to the company. It is the purpose of this discussion to suggest for consideration possible weaknesses in the plan, as well as possible improvements.

The authors do not state whether or not a revision was made in the plan on January 1, 1929, or at the subsequent six-month interval. It would no doubt be interesting to know what, if any, revisions have been made since the wage-incentive plan was inaugurated.

In connection with these revisions, if any have been made, it is evident that the continued future success of the plan must depend largely upon the confidence of the employees in the management. As long as the employees feel that the budgets have been justly established, that confidence will be maintained and operation costs will be kept on a low level. If the budgets are at any time revised downward without justifiable reason, so that difficulty is encountered in earning a satisfactory bonus, the confidence of the employees in the management will be threatened. This may eventually result in disgruntled employees and high costs of operation. This phase of the plan can only be tested after the plan has been in effect for several years.

It is also worthy of note that due to the method of establishing the original budget, the department operating with the greatest inefficiencies participates for the first few months in the largest bonus. That is, the department which, prior to the inauguration of the plan, is operating at "rock bottom" costs has less of an opportunity to reduce further the cost of operation, as compared with the inefficiently managed department. A premium reward is thus paid for the first few months at any rate for inefficient management. It would appear that a more accurate basis than past experience could be obtained for establishing the original budget. Time studies have been employed for such departments in determining the effectiveness of labor

[6] Engineer in Charge, Time Study, Standards and Budgets, B. F. Goodrich Rubber Co.

and the establishment of labor cost budgets, even though piece rates or direct bonuses are not used for direct compensation of the employees. The degree to which labor is fully utilized in a department is ofttimes a pretty accurate measure of the degree to which materials and equipment are utilized.

Furthermore, in the concern with which the writer is connected, the employees in several corresponding service departments mentioned in this plan are compensated by direct premiums paid to them under the Bedaux plan, after the work in the departments has been properly time-studied. These departments are timekeeping, tabulating, plant transportation, motor trucks, warehousing, and janitor service.

It is also to be realized that the bases used in this plan fluctuate from time to time due to the varying effectiveness of the management in the production or base departments. Thus, the number of employees in attendance in a production or base department may vary from time to time, not necessarily because of any variation in the volume of work, but rather because of the variability in management effectiveness. This is offset to some extent by use of the moving average in the determination of monthly budgets, expenses, and bonuses. It is conceivable, however, that the number of employees in attendance over a period of months may be in excess to actual needs, thus increasing unduly the budget and consequent bonus for the transportation group or any other group, the bonus for which is computed on the same basis.

Despite these possible shortcomings, the Newport News Shipbuilding and Dry Dock Company is to be congratulated on its courage to attempt such an undertaking. The results which are being attained are the same as all industrial managers are striving to attain. The authors suggest that the plan "may not be regarded by some as scientific." The savings effected are being immediately reflected in the accounting records of the company. The plan is sufficiently flexible as to permit the application of scientific methods from time to time as experience dictates.

K. T. Keller.[7] Most of the fundamentals are applicable in any manufacturing plant. It is felt, however, that these fundamentals could be applied more directly by means of predetermined operating costs which would be the governing factors in balancing the budget for all departments, including the service departments, with the productive output at a level which would assure a profit from the plant operations.

When a six months' average of expense is used, there is no indication that the expenses for the various departments were normal or that the volume of output justified the expense, even if the expense was considered to be at a normal average. Hence, the service departments should first be studied, in the following respects:

To determine the necessity or relative importance of the work, as non-essential functions may be developed through errors in judgment or they may be continued after a temporary necessity has passed and relatively unimportant functions may be overdone.

To determine the man-power required to carry on the necessary functions. Requirements should be based on actual time studies, either of the operation itself or of the operation served, wherever possible, as the time studies provide a direct method of measuring the non-productive in proportion to the productive. The requirements should be divided into variable and constant (or stand-by), but the constant should be limited to the fixed charges and to the minimum expense necessary for plant protection and maintenance, and for the barest skeleton of an organization, inasmuch as there are very few operations which cannot be curtailed or suspended when production approaches zero.

To determine the responsibility according to the department which will authorize an expenditure. In budgeting or in setting up a bogey for budgeting, it is believed that the responsibility should be fixed on the department originating an expenditure. Hence, the plant engineer would be responsible for all maintenance rather than giving any allowance to the various other departments. The expense as a whole should be divided to show the controllable and non-controllable. The non-controllable would include expense which has no relation to production and cannot be controlled by the manufacturing supervision, as depreciation, taxes, insurance, write-off for inventory shrinkage, plant protection, accounting, etc. The controllable would include inspection, stock handling, tools, supplies, etc. This separation in the budgets and in the expense statements shows the non-productive expenditures which should vary proportionately to production and also shows where it is possible to reduce when adjustments are necessary.

The complete study of the expense should be made on the basis of the requirements when the plant is producing on an average basis. The expense by departments and in total compared with the average productive labor gives the normal burden percentages for the plant and for the various departments. This percentage should be used in calculating the selling price of the product and should be the permanent bogey or fixed burden for controlling the budgets for all expense, excepting the fixed charges. The application of the bogey percentage against the productive labor for any schedule would give the permissible variation in the expense. The result is a standard manufacturing burden cost.

This plan does not provide a general incentive plan for expense reduction, but incentive wage plans can be incorporated wherever applicable. However, when the expense is properly studied, and the budgets controlled accordingly, there is no margin over requirements. Rather, it requires careful supervision to keep expenses within the budgets. Requisitions for additions to the force and for purchases of material must be checked with the budgets and properly approved.

The cost of operating this plan is very small. A budget supervisor and one or two assistants are all the special force required. The time study, employment, and timekeepers are tied in to the labor control. The material department, tool stores, and purchasing department are tied in to the material control. Expenditures not included in the budgets are not authorized. The accounting department makes daily reports of expenditures which are checked against the budgets. An annual bonus may be used as an incentive for the supervision.

It is apparent the plan set up is from actual findings and could be improved by actual studies.

C. W. Lytle.[8] The cause of good management is distinctly furthered by this paper. Although the authors may not be the first to apply job standardization and incentives to service departments, the thoroughness with which they have made the application and the very scale of the work makes the case peculiarly valuable. The paper might equally well have been named "Standardization of Work in Service Departments." In fact, this phase of the subject takes up the bulk of the paper. On the other hand, it has been the difficulty of such standardization which has delayed the application of incentives to this work, and the incentive is of course the immediate object of such work. As a student of incentives, therefore, the writer is glad the authors have given the paper an incentive title and this title will lead many to read it who are interested in the incentive question. It would seem that the procedure here described

[7] Dodge Brothers Corporation, Detroit, Mich. Assoc. A.S.M.E.

[8] Director of Industrial Cooperation, New York University, New York, N. Y. Mem. A.S.M.E.

is the most practical for such work. The detail would naturally vary. The formula for the budget task is made up of two parts, a constant and a variable, the former representing that amount of cost for the given department which is irreducible whether the department is producing or not. The latter part is a simple product of some carefully selected factor and the number of men or dollars involved. In short, the fundamental formula is not new, but is here presented in such a way that it is likely to be given renewed attention.

In explaining the use of this general formula, the authors mention that there are errors involved, but that they are inconsequential on account of the sharing feature of the incentive arrangement. This is an old principle—the principle which led Mr. Halsey to use the constant sharing type of earning arrangement at a time when all tasks were estimated and therefore were subject to considerable error. Graphically, this means that on a two-variable chart, the horizontal axis being efficiency and the vertical axis being wages, an estimated task is usually anywhere from 40 to 65 per cent of the more accurately set tasks in direction production. The earning curve in a sharing plan therefore starts at a low task point and reaches the desired high-earning field at the efficiency point most likely to become the location of average response. Conversely, these earning curves avoid the possibility of reaching too high an earning field for the average response point. In short, then, the selection of a constant sharing type of earning curve is exactly the correct practice for this kind of a task in shop or office.

What appears to be a very different matter is the practice of adding the amount of premium to the budgeted cost at the end of each successive month. No doubt the reason for this is to make the budgeted task include the whole labor cost whether the work is done with a large amount of day wages and small premium or a less amount of day wages and a larger premium.

From a cost-accounting point of view this is justified, but from a psychological point of view it certainly is not. It is a situation where the wage practice should be somewhat divorced from the costing practice. In fact, there seems to be no reason why the task cannot be equally well measured by all costs exclusive of premium and the factor adjusted so as to make the premium whatever it needs to be. It is certainly a difficult practice to justify to employees and might be interpreted as a new form of rate cutting.

The Rowan variable-sharing plan substitutes for the arithmetic fraction of sharing a variable or algebraic fraction of sharing which allows less and less premium as the efficiency increases. The fraction is so fixed that the maximum wage including premium can never exceed twice base wages, and in practice can never come even near this amount. This plan is mentioned because it has never seemed fair to American employers and is not used in this country, excepting for tasks extremely onerous.

Now, if the plan under discussion needs to have extreme protection for the employer, it can do so by using the Rowan principle. The writer is not prepared to recommend that principle very highly, but it is preferable to the practice of allowing the premium of a previous month to affect the task of a successive month. Perhaps this part of the paper is misunderstood, but in any case the authors should give their attitude on this point.

The authors have been most modest in describing their achievement. A great deal of their success has been due to their spirit of enthusiasm and their very human pains taken in the matter of training.

Authors' Closure

The discussions have been very much to the point, and bring out several important features of budgeting (or task setting) and bonuses which should be considered for any plant or department, and should perhaps have been more fully covered in the paper. The following features discussed should be emphasized and explained further:

From discussion by Mr. Zuelow: "In the case of general service departments the several functions are carefully analyzed and task standards established on all major controlling factors involved;....further and more scientific study into this subject is imperative if satisfactory and permanent improvements along these lines are to be properly guaranteed for the future."

From discussion by Mr. Jones: "The difficulty of preparing incentive plans for service-department employees should gradually be lessened as tasks tend to be standardized....There might be developed some possible interconnection between group-incentive plans and the total company profits in the lean years."

From discussion by Mr. Hecht: "The incentive plan at South Philadelphia is not confined to the service departments, but applies also to the supervisors and foremen of the so-called productive or operating departments....While past performances over several years were taken as a basis practically all expense accounts were modified before bonus earnings could begin. Some of the expense items were increased and others decreased. The standard expense allowance at Newport News is determined by either the total labor cost of the department or the total direct labor payroll. At South Philadelphia [due to 35 to 40 per cent of the operations being on an overtime basis] productive hours were set up as the determining base."

From discussion by Mr. Dildine: "It is evident that the continued future success of the plan must depend pretty largely upon the confidence of the employees in the management."

From discussion by Mr. Keller: "The service departments should first be studied to determine: (1) Essential and non-essential functions, (2) the man-power required to carry on the necessary functions, and (3) the responsibility for service expenses should be fixed on the department originating the expenditure....The complete study of the expense should be made on the basis of the requirements when one plant is producing on an average basis....The result is a standard manufacturing burden cost."

In the large plant under discussion in the paper, budgeting the expenses of all departments, both operating and service departments, had been in effect for two or three years prior to the introduction of wage incentives or bonus plans in the service departments. During this period, a close analysis and study of the functions of each service department was made, and the budgets revised, usually downward, until they were as fair and reasonable as could be predetermined at the time. These tasks or budgets were watched very closely by the heads of the respective departments as well as independently by the budget engineer, under the direction of the general manager. In addition to this, a special committee of seven members on "overhead reduction" was organized, and for two years prior to the group bonus plans described went into the details of organization and expenditures for each department in the plant. Through these means, the expenses were considerably reduced, in practically all departments, and the expense budgets, as finally revised before group bonuses were inaugurated were almost met or beaten for all departments. In other words, it took over two years to prepare the way for the group bonus plans described, and it would have been a great mistake to have put the bonus plans into effect first, then afterward to have made analytical studies, including time studies and the elimination of unnecessary functions. Perfection was not reached, of course, in setting the bogeys or budgets, and never can be, for that matter, for reasons brought out in the paper. The introduction of the bonus plans increased the interest, has sustained the interest, and has led to

many improvements through stimulated thinking that had not occurred to any one during the previous two or three years of preliminary study. The points brought out in the quoted discussions were recognized by the authors, when they said: "The present plans make it easier to go further and more scientifically into the whole matter."

For a plant working any considerable amount of overtime, like the Westinghouse plant at South Philadelphia, it is necessary for greater accuracy to use "man-hours" as the basis for output, rather than "number of employees in attendance," or "dollars of labor." Judgment must always be used in deciding between simplicity and accuracy. If all the records of a plant are kept in "man-hours," this should be the basis to use, in all cases.

Professor Lytle makes a good point of the method used of including the bonuses as part of the actual costs or expenses of the service departments, and then dividing the net savings equally between the employees and the company. Theoretically, it might be better to exclude the bonuses from the costs, for psychological reasons only, and then figure out the resulting division of "gains" as between the employees and company, say one-third to employees. In practice, however, this feature has never caused any trouble, as the plan was explained and agreed to in detail by the prospective participants in the beginning.

The important thing, after all, is mutual confidence between men and management. In the plant discussed, they have an "employees' representation plan" or "works council," through which all questions affecting the workers, hours of work, wages, incentive plans, piece rates, and earnings are freely discussed, with all data and facts known, which has made for confidence and a sense of fair dealing.

It will be noticed from a study of Fig. 3 that the budget line or "expense budget normal" is a straight line, instead of "drooping" as the actual cost line does; therefore as the output increases the bonus earnings increase more rapidly than the improvement in efficiency, corresponding to the idea of the Taylor differential piecework system. This feature makes the over-all success or profits of the company of great interest to bonus participants, since the total output (labor) or volume of sales makes for greater profits, other things being equal. This also takes care of the point raised by Mr. Jones, in an inverse manner, of paying larger relative bonuses when the company itself prospers greatly, and vice versa, paying very small bonuses in lean years. As to whether a company can "afford" to pay bonuses in lean years, however, that is a different matter; for if a wage-incentive plan of any kind does not assist in cost reduction and a better result for the company it should not be installed at all. This is important. If a company is losing money, as the large company discussed in the paper was, three years ago, then is the time to consider bonus plans, in order to put the company in a position to make money.

It should be remembered that wage-incentive plans for operating departments are much easier to develop and install in a plant than similar plans for service departments. There are many reasons for this. Therefore the start or beginning should usually be with the operating departments, and in the plant discussed this was done, as mentioned in the paper, but the description was confined to the work in service departments. It is stated that "incentives were already in effect before service department bonuses were started, with excellent results, not only for productive or direct labor employees, but for practically all executives, major and minor, including foremen and gang bosses."

One other matter should be made clearer: The budget formula $B = K + Pn$ is merely the equation for the line representing the "expense budget normal," in which K is a hypothetical or unreal constant equal to the "stand-by" charges when the department is practically closed down. In practice, as brought out by Mr. Hecht, the expenses of a department at this "mythical zero" of operation are practically impossible of determination with any accuracy. The "actual" figure for K, if it could be determined, would probably be lower than the figure used in the empirical formula. The formula is really determined after the line for the "expense budget normal" is settled upon and drawn. Actual spots for various conditions of output, when the details of the expenditure are analyzed, month by month, show the actual "trend" of departmental expenses, as the volume fluctuates; that is, they determine the "slope in gradient," of the line $B = K + Pn$, or the value of the expression Pn, as well as the "approximate position," up or down on the chart, of this line. The final budget line being settled, the value K is then calculated.

MAN-52-6

The Training and Recruitment of Auto Mechanics Through Factory Sources

By WILLIAM F. RASCHE,[1] MILWAUKEE, WIS.

This paper treats of the selection and training of automobile mechanics through factory sources and outlines what the evolution in development of service facilities and service workers has been, what the present-day requirements are, what type of individual should be selected for training, and how a factory training school must be set up with respect to places of instruction, the preparation of a curriculum, the organization of instructional material, and the training and supervision of instructors.

THE evolutionary forces controlling American business are compelling industry to make changes to meet new business conditions. These forces undoubtedly are not wholly welcome to business leaders who are coerced by this evolution in business to make extra efforts to secure the same financial returns they received formerly with a lesser expenditure of energy and money. Sharp competition is forcing them to refine their methods and practices in order that a greater industrial efficiency may be attained.

The automobile industry is no exception to this new development. Evolutionary processes are as certainly at work in this industry as in others, and the captains of industry operating in this field are as hard put to guide their enterprises safely through economic storms as are those in other fields. The effect, so far as the public is concerned, has been beneficial for the users of motor vehicles, who are now buying better motor cars at lower prices and securing motor-car service not equaled in the past.

It is the service phase of this industry to which this paper is devoted. One need but consider what has transpired in the last few decades to appreciate fully the significance of the great interest that automobile manufacturers are taking today in motor-car servicing and the marked efforts they are making to improve their motor-car servicing facilities for the benefit of the users of the vehicles they manufacture.

The prevalent practice of a large part of the owners of cars to trade cars in after a season's driving had its origin to a certain extent in the earlier unhappy experiences of automobile users who found it well-nigh impossible to have their cars satisfactorily repaired when mechanical difficulties developed in their cars and that required attention. A certain traditional overhang still exists which influences a large part of the present-day car users to have little faith in the integrity of the average automobile garage mechanic. They firmly believe that the safest way to avoid unsatisfactory treatment is to trade in their cars before the services of an automobile mechanic may be required. Indeed, one does not need to look far to find many car owners who will say that a trip to a garage to have a repair made is usually merely the beginning of a whole series of other motor-car troubles which seem to follow promptly whenever a car has made its initial trip to the service garage.

Much of the blame for malpractice in the auto-mechanics field unquestionably belongs to the blacksmiths and horseshoers of an earlier day whose occupational life was disturbed and finally dislocated as the automobile grew in popular favor as a means of transportation. These men, for the most part, were compelled to seek new occupational outlets, and many of them turned their smithies into garages and announced to the somewhat helpless traveling public their readiness to repair cars that needed repairing.

Automobile owners and users received at their hands what one would expect to be the case under such circumstances—namely, poor service at a costly price. These novices, like others who pick up new trades on the job, were experimenting at the expense of the public, in this case the car owners and car user.

Naturally, while a generation of blacksmiths was thus serving its apprenticeship in an adopted occupation, a car-using public had its difficulties in securing the kind of repair service it wanted, and looked for a means of escape. In this early unhappy situation automobile salesmen found a new market for new cars by inducing car owners to buy new cars on a trade-in basis, and thereby passed on to other people also desirous of owning cars, but possessed of smaller pocketbooks, the repair problems from which the more financially able buyers of cars sought to be relieved.

But even the used-car trade could not be long imposed upon. The ever-increasing number of car users, as well as the ever-increasing number of new and used cars on the market, hastened a public demand for more and better service facilities and more honest treatment. Manufacturers soon realized that the public was looking to them for protection, and they therefore gave attention to the problem of providing dependable and honestly priced service to the public. Manufacturers saw the need of announcing standardized prices for both labor and materials required in car servicing in order that the public might know just what it could expect to pay. Furthermore, appreciating that car users wanted some assurance that they were not placing themselves in the hands of unscrupulous or incompetent people, manufacturers selected with considerable care honest and competent persons capable of meeting the public needs and demands. To those who could thus qualify, manufacturers gave their approval, and approved service stations were designated through the use of the term "authorized service."

Early Improvements in the Service Field

But automobile manufacturers have learned that the selection of properly trained people for these responsibilities is no easy task. They found that there was no ready-made group of trained mechanics available to send out to render the service that the public demanded. They directed their efforts, therefore, to the training of experts who could be sent to branches and dealers to set up service facilities and to train out in the field men of potential ability in the proper servicing of the particular types of cars their employers manufactured. This movement was a step forward, and it put service work upon a better and more satisfactory basis than had been the case before. However, it resulted merely in the training of auto mechanics as such, men capable of doing the mechanical work required in service stations. It was

[1] Principal, Milwaukee Vocational School. Formerly Educational Director, General Motors Truck Corporation, Pontiac, Mich.

Contributed by the Committee on Education and Training and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

a strictly vocational development in a special mechanical field and did not go beyond that. It had not reached the level on which service training must be done under present-day conditions, which require, in order that the demands of an exacting public may be met squarely, that the auto mechanic be in fact a mechanic plus, in which the plus stands for a number of additional qualifications that were not sought for especially in the earlier attempts at selection. It is indeed a far cry from the early "blacksmith made over into an auto mechanic" type of service man to the present-day efficient individual who greets the customer who is willing to accept the up-to-date authorized service of the better service stations.

The Selection of Trainees

At this point it may well be asked what, beyond the ability to repair cars, is required of those who would serve the public as competent automobile mechanics.

Field contacts made by the author with service-garage proprietors of reputable standing in various communities and his contacts with the service division of a large truck, cab, and coach manufacturing corporation, as well as observation of the educational practices of several technical and vocational schools which train service men and automobile mechanics, have led to the conclusion that the ideal automobile mechanic and service man should possess as a minimum the following qualifications:

1 All the necessary personal traits which attract instead of repel customers.

2 Thorough knowledge of the construction and functions of the makes of vehicles and their parts which he claims to be able to service or repair.

3 Ability to make repairs properly with the requisite speed and to have cars in a fit condition to be used by customers when they are called for.

4 Ability to sense potential sales of parts and to recommend their purchase when such transactions would actually confer a service upon customers.

5 Ability to sense, from the condition in which cars are brought in for service, a driver's mistakes which tend to shorten the usefulness of cars.

6 Ability to instruct so as to be able to teach customers how they may use their cars more intelligently in order that car users may derive a greater service from the cars they operate.

7 Ability to tell whether car troubles are due to defective workmanship at the factory, defective materials, or abuses for which the customers are responsible.

8 Enthusiasm for the product his employer sells and familiarity with the general policies of the manufacturer who builds the product.

Obviously, a mere mechanic, even if he knows all about repairing a vehicle, does not meet present-day requirements entirely, and those seeking timber for training must look for something in addition if the individual to be selected is to qualify in an all-round way. He must be a person of pleasing personality and must possess those qualities characteristic of a good salesman as well as those of the expert mechanic.

This wider range of qualifications adds to the difficulties of selection and recruitment. It is surprising how many people unsuited for the work seek to enter the auto mechanic's field. Many auto mechanics are selected by the dealers and service stations who need them, although it is questionable whether such chance selection in the field may be considered scientific. The one advantage which selection in the field has over selection at the factory is perhaps a lower turnover in service, because the selected individual usually has his home interests in the community where his services will be required. On the other hand, selection at the manufacturer's plant, through scientific selection through an efficient personnel division, is likely to insure a much better type of trainee.

Most large manufacturers now conduct service schools, either at their plants or at service training centers, in cooperating engineering schools where engineers also are trained. If their personnel divisions have set up scientific methods of selection in their employment departments, potentially good material for training will be secured.

An effective formula for selecting suitable trainees will result in the selection of:

1 Young men possessing average or above average mental ability who are eager to learn.

2 Men whose education is never less than that offered in a common school and preferably those who have had high-school training or its equivalent.

3 Vigorous men of good health who are physically capable of doing any task connected with the service repair work on an automobile.

4 Men of mechanical aptitude.

5 Men of good character with pleasing personalities.

Mental ability can be determined roughly by noticing the relationship between school age and school achievement as indicated by the scholastic record of the candidate. It can also be tested with mental tests, of which there are many kinds now on the market. Many of the more reliable tests have been used by various industries as well as schools.

School achievement is a matter of record and should always be considered, since it indicates how diligent the candidate was at the time he attended school. Training in physics, chemistry, and mathematics is a very desirable element in the trainee's scholastic equipment.

Physical fitness is a matter to be determined through physical examinations. These should be done thoroughly in order that accepted trainees may be minus any defects which will operate against their success in the occupation.

Mechanical ability is best tested by trial in the factory shops, especially in the manufacturing, assembly, electrical, and testing departments.

Personal characteristics are a matter for investigation. Inquiry should be made concerning the candidate's ability to get along well with others, his character traits, and his general standing in the community. Disinterested parties who know him should be consulted when securing this information.

This information should be supplemented, however, by further information secured from department executives who control the activities of the trainee while he is in their departments, in order that the statements of those who were given as references may be verified.

High-school councilors or vocational guidance officers in public-school systems are often prepared through their records to supply data which will give rather complete information concerning personal traits, especially any that show leadership qualities, aggressiveness, resourcefulness, and initiative.

The Factory Training School

A factory training school to be successful must have (1) a satisfactory place of instruction, (2) an appropriate curriculum, (3) properly prepared instructional materials, and (4) competent teachers. In addition there must be a functioning administrative plan to insure a high quality of instruction and the proper routing of the trainees. Furthermore, a direct contact must be maintained with the field in order that curriculum revisions may be made in the light of field experiences that are acquired in connection with the release of new car models.

The Places of Instruction

The places of instruction in an effective training set-up will be of two kinds. First, there will be the regular shop departments to which trainees will be assigned to tasks on the job, and second, a special demonstration classroom equipped with illustrative materials, models, and other necessary equipment.

The special demonstration room in such an arrangement should be exclusively in the control of the person who is in charge of the instruction, and in this respect it differs from the shop departments to which trainees are assigned. Because the primary purpose of shop departments is to turn out productive work, there is always great danger that foreman or sub-foremen, under the pressure of the demands of a production schedule, will tend to neglect the instructional work whenever they become hard pressed. Under the pressure of heavy schedules they are very likely to assign trainees to jobs that happen to be immediately available, but which are not always the kinds of jobs which serve instructional purposes best. For this reason the one in charge of the educational work must make a careful analysis of everything that is going on in the various departments and designate what jobs are to be done in the production departments, at what locations the trainees are to do their work, and under what conditions. This should never be left to chance, but should be specified in a typed or printed schedule which may be consulted by the executives in charge of the departments to which trainees report so that they may always know exactly what is expected of them. When such written guides are available, the administration of the educational work under the control of department foremen or subformen becomes much easier and very much more effective than when assignments are left to department heads exclusively.

In order that there may be a minimum loss of time for executives, instructors, and trainees, it is also well to have a floor plan of the shop departments on which are indicated the assignment locations. On this plan should also appear such symbols as will indicate what the sequence of travel through the department is to be. When such graphic guides accompany the typed or printed schedules, the administration of the shop instruction program will not be difficult.

Demonstration Equipment

Some things should be said concerning the special demonstration classroom. This should not be any old place in the plant, but one where good facilities for ventilation, light, and heat exist. It should also be located in a place where it is close to the operating departments to which trainees must go to do their practical work.

In the demonstration room there should be models of the many items that go into the construction of a car. These should be set up in such a way that the group to be instructed may see readily the underlying principles of operation of the various practical units with which they are concerned in the shop departments of the plant and with which they must deal later when they are employed at service work in the field. This classroom should also be very liberally supplied with good diagrams and graphic charts of everything that is placed in the motor vehicle. The supply of graphic-chart material should be extensive enough to present to trainees not only the mechanical and electrical arrangements of the current models, but also the differences existing between the latest and earlier models. Diagrammatic and chart material should also be supplemented with slides and films which can make the visual instruction more effective.

This classroom should further be supplied with a library of technical books which serve as source materials for trainees to consult in the hours when they are away from the plant and even during the study periods while they are at the plant. Those in charge of the instruction should be alert to the release of new technical books in order that this library may be constantly kept up to date. Naturally, the library should also contain trade catalogs of manufacturers whose products are used in the car made at the plant where the instruction is given. In addition to this, the manufacturer's own trade catalog, parts books, instruction manuals, and other practical literature should be made available.

It is needless to say that in addition to these items suitable furniture consisting of tables and comfortable chairs (but not too comfortable) should be provided.

The Curriculum

In any type of school the efforts of the teaching staff must be based upon a properly conceived and developed curriculum. This holds equally true for factory schools training people for service work.

Several factors must be kept in mind in setting up the proper curriculum. It is essential, first, that an analysis be made of everything that is built into the product of the manufacturer. This is nothing other than an inventory of all the tools, materials, skills, and knowledges that are employed in producing and repairing motor cars. A thoroughly competent service man must have mastery of all these elements before he can function effectively in the field at service work. The cue for making such an inventory can be secured from the parts books, instruction manuals, and other literature which the engineering division prepares from time to time as new models of cars are released.

The second factor which is not so easily determined consists in cataloging all the principal difficulties that the users of the product are meeting under actual transportation conditions throughout the territories where the product is used. The experience of manufacturers has been that the difficulties which are experienced with various types of cars do not run with the same frequency for all types. In one kind of model difficulties seem to localize in places entirely different from those which apply to other models, and so it is necessary following the release of each new model to keep closely in touch with car users in order to determine what kind of difficulties are developing for which a peculiar type of service may be required. This calls for the analysis of a stream of letters which come to the home office from branches, dealers, and service stations. These letters should be analyzed not only by the engineering and manufacturing divisions of the corporation, but also by the service school in order that service people may get the specific kind of training which will make them competent to cope with these difficulties. Because of this variation in the types of difficulties from year to year, some corporations are quite convinced that an annual return trip to the service school by field service men is highly desirable in order that they may get the additional training necessary to bring them up to date.

Instructional Materials

After an analysis has been made of all the specific elements concerning which a service man must receive instruction, it is important that these elements be organized into an outline of instruction and put into an instructional sequence that is the most effective for the learner to follow in acquiring the knowledge and ability which he must possess before he can function as a service man. Experience has shown that the logical sequence is not always the best sequence for instructional purposes. Good teaching calls for a proper psychological development of an outline of instruction. Rarely, if ever, do logical and psychological sequences coincide. Because they differ more often than not, it is incumbent upon the instructor who prepares the outline of instruction to place the elements to be taught in such a sequence as will insure the easy transition from one element to the next.

Stated in other words, this means that a competent instructor always recognizes the learning difficulties that are bound up with the various things to be learned. When the instructor keeps this principle in mind, he is naturally facilitating ease of learning, but must be sure that in the total range of instructional elements offered all the vital elements have been incorporated into the outline of instruction. This building of a proper outline of instruction is just as important as is the original analysis in which all the elements are inventoried irrespective of their significance in an instruction scheme.

Units of Instruction

Following the preparation of an outline of instruction it is necessary to prepare the individual units of instruction in which are presented informational matter, illustrations, type solutions, and problems. These individual units should be prepared in mimeographed form or printed for distribution to the trainees. Each unit should contain at the beginning a statement of objectives so that the student may know exactly what it is that he is to do. Following this statement of objectives there should appear a paragraph or two giving such general information as may be necessary to orient the student with respect to the type of work treated in the unit. Following this should appear a set of specific directions if it is instruction bearing upon learning how to do some type of service work or a discussion of the specific work if it is related information that is to be acquired. No unit instruction sheet is complete unless it presents to the learner specific problems to be solved by him. While it is perfectly proper to introduce specific information in units of instruction, and even to present the exact order for doing things, it is essential that as much opportunity be given to the student to do original thinking as it is possible to incorporate into the course, for his success in the work will depend very largely upon his power to analyze for himself typical motor car problems such as come into service stations for correction. It is good practice in the beginning units of any series to make the informational set-up complete and then to lessen it somewhat with each of the succeeding units. This will afford the student a sufficient background of knowledge which is essential for any one who would do original thinking and also will furnish the challenge which must be present in the course if it is to be effective.

It will be noted, therefore, that the complete cycle in the preparation of instruction involves three steps—(1) the analysis of the field, (2) the organization of the outline of instruction, and (3) the preparation of the detailed units of instruction.

Training Service-School Teachers

While it is perfectly sound to get practical instruction in the regular shop departments of the plant, it is fallacious to assume that foremen and sub-foremen are by and large good instructors. The day will probably come when foreman training will have become general and when every department head will not only be a good supervisor and manager, but also an able instructor. That happy day has not yet arrived in industry, and for that reason extra precautions must be taken by the training department of an industrial plant whenever it is desired to utilize the services of production foremen and their assistants in the instruction of service students. This presupposes in the first place that the person selected to head the service school is himself not only a good teacher, but a good teacher trainer. He should be thoroughly familiar with the principles of learning and teaching and must be in a position to give the foremen and sub-foremen of shop departments practical instruction which will enable these men to do effective teaching work with such men as are assigned to them for training. When such department executives do not have this preparation, it is important that arrangements be made to bring these men into training in order that they may acquire the teaching ability and technique which are essential for successful work. The head of the service school may very well prepare a series of lessons which will treat specifically of the learning-teaching problem. He ought to supplement his class work with mimeographed instructional material and a bibliography on education suitable for industrial work so that enterprising foremen and their assistants may make supplementary outside preparation for this work.

The Teaching Task

Many people in teaching positions think they are teaching when as a matter of fact they are not. Meeting groups of learners or talking and lecturing to them is not teaching. Telling and teaching are never identical. Telling may or may not be a part of teaching, but can never take the place of it. Granted that the trainees are people who have capacity to learn in the field in which they are seeking instruction, it is safe to assume that "the teacher has not taught until the student has learned." Just as it is possible to measure the products which are turned out by a production department, so too is it possible to measure the productive work of a teacher in a service school.

A competent instructor will be able to set up checking or testing devices in connection with every unit of instruction, as well as composite checking devices for a series of units, and if he is efficient, he will be constantly testing the progress of his class to make sure that each student in the class is securing just exactly what he should secure. If the testing work is thoroughly done in connection with any practical course of instruction in a service school, it will be possible to certify in a specific way what abilities the trainee possesses at the time when he finishes the course. In light of these facts no trainee should be released to the field who is unable to meet the minimum requirements that, by common agreement of those who are familiar with the work, should represent the fund of knowledge as well as the range of abilities required for successful field practice.

It may be said that whenever an outline of instruction is administered in this thorough way and it is known that there can be no certification until all the minimum requirements have been met, the trainees will get down to business at the very outset of their course of instruction.

Daily Schedule for the Students

It has been indicated that the student will spend his time between the shop departments and the demonstration classroom. There are various ways of dividing a student's work day. No arbitrary plan can be mapped out for this work, because conditions will vary with the varying requirements of different corporations. However, it may be said in general that at the beginning of the course of work probably considerable time should be given in the classroom building up the base so that students are furnished with an adequate background for their work. Since the work of a course will divide itself into a number of large blocks of instruction, it is good business to engage each block of instruction by spending sufficient time in the classroom to get the theory concerning it, and then to follow this with the practical work in that block of instruction in the appropriate shop department where the practical work is going on.

In order that students may have the opportunity to pool their daily experiences, it would be well to close each day with an hour of work in the classroom where the service instructor may check up with the students concerning their day's experiences, direct them to supplementary materials which they may need for outside study, and conduct such discussions as may be helpful. In this connection it may be said that it is good business to call in experts of the engineering, manufacturing, and service

divisions of the corporation and specialists from outside corporations which are suppliers for the corporation conducting the service school. In this way the students will secure a richer fund of knowledge than is possible when they depend entirely upon their experiences in the shop departments. In bringing in outside people to the school, either from other divisions of the corporation or from outside corporations, the head of the service school should attempt to secure people who are as nearly as possible good instructors as well as experts in their fields.

Length of Courses

The length of courses will vary depending upon the objectives to be served. Every company can afford to keep in training quite a number of men selected through the personnel division who will be kept in training from six to twelve months before they are ever released for service work in the field. If their instructional program is thoroughly organized, such men can be depended upon to fill rather important assignments provided the trainees at the time they begin training have all the potential qualifications given in the preceding list.

Every corporation service school, however, will have to deal with the short-term trainees who come in from the field for such periods as one day, one week, two weeks, and one month. The shorter the time available, the more abbreviated the instruction must be and the more important it becomes for the builder of the course of instruction to select those items for instruction which will be of most service to the people who are to be taught. People who come in for one day and one week are usually folks who are seeking to brush up on certain phases of the work concerning which they desire to have additional training. It will thus be noted that, in order to meet the varying requirements of the different types of learners to be served, the head of a service school must arrange his work so that it can be administered in the most flexible manner.

Personnel Records

Complete personnel information concerning factory-trained service men should be kept. These records should in the main give the usual personnel data found in complete employment office records, but in addition should cover three classifications of items to be entered as the learner progresses with his work.

The first classification should be a careful evaluation of the learner's personal traits, to be determined periodically by the various shop-department instructors and the head of the service school. Such traits as resourcefulness, initiative, industry, willingness to cooperate, and self-control should be carefully noted and recorded. However, before shop executives are asked to make such evaluations, they should be taught how to rate personal traits and characteristics.

The second classification should cover the learner's achievements with respect to his theoretical studies in the service classroom. The record covering this will indicate how well the learner can think and whether he understands underlying and related principles.

The third classification has to do with the learner's shop performances. The shop record should state how well the learner can diagnose motor-car troubles, how efficiently he can correct them, and with what dispatch.

The foregoing items when reliably gathered tend to correct the initial estimate of the learner secured at the time an investigation of his qualifications was made by those responsible for selecting trainees.

The foregoing discussion has treated of the training of auto mechanics through factory sources. The reader should keep in mind, however, that it is not possible to train all the men required for service work at factory schools nor even to select them there. The factory school can do only a part of what is required. The vocational schools throughout the land are in a splendid position to contribute also and their facilities and faculties should be utilized fully to meet local needs, for the solution of the service problem can be had only through using all the available agencies, of which factory schools are only one.

Summary

The organization of a modern service school for the training of auto mechanics through factory sources requires careful analysis of the work to be done, proper organization of the instructional material, the appropriate equipment of the shops and laboratories to be used for instruction, the selection of a highly qualified type of trainee possessing specific personal traits, business qualifications, and mechanical abilities, and instructors who are not only familiar with the subject matter of instruction, but who are well qualified to teach. No service school, if its work is to be done well, should ever certify trainees until through a system of checks it has been determined that they have met certain minimum standards and requirements to be agreed upon by those competent to set up such standards.

Discussion

Ray H. Sullivan.[2] There are several factors which have affected, now affect, and will affect the training and recruitment of auto mechanics through any source. A careful study of the problem discloses a few which are outstanding and which demand consideration in their solution, as follows:

1 The automobile industry's rapid growth.

2 Its geographically scattered application.

3 Mass production methods which practically revolutionized all industry and which eliminated factory labor for use as mechanics.

The writer believes that the leaders in the automobile industry wholeheartedly and sincerely welcome whatever may force them to refine their methods. They have always indicated both the desire and courage to attack and solve the multitude of problems which were incident to the tremendous expansion in the industry. He also believes that the industry is fortunate because in most communities, preceding the general use of the automobile, there was a mechanic who perhaps worked in a blacksmith shop and was at the same time a horseshoer and carriage maker. Certainly this type of more or less all-around mechanic filled what would have been decidedly a vacant space in the automobile industry. The very fact that he was more or less an all-around man was diametrically opposed to the mechanic in the automobile factory, due to the division of labor, and he was probably a life-saver to the industry.

Frequent and revolutionary experiments and changes were made by different automobile manufacturers which complicated the auto mechanic's job. Only some sort of versatile mechanic could possibly have spent the time and thought to do servicing of any type for a considerable period in the industry. The automobile industry has drawn liberally from this former blacksmith source, and some of its leaders today were trained in the fundamentals of mechanics through the hard school of experience as community blacksmiths. Consequently, many of these smiths were really forced to turn their shops into garages because of the public's insisting on some place to have their cars repaired, rather than the opposite.

We possibly are likely to stray too far from the advantages which came from knowledge gained from work applied on the job.

[2] Personnel Director, Fisher Body Corporation, Detroit, Mich. Mem. A.S.M.E.

By "on the job" is meant just as the work actually is presented by the customer, rather than any theoretical set-up.

The problem was and is really one of making almost instantly available the services of an unbelievable number of people scattered all over the world to repair and service products of the industry.

It does not seem, either, that one can reasonably charge the prevalent practice of changing cars annually to unfair treatment on the part of service men. Is there not a sort of natural desire on the part of every one to keep up to date—to get new things, whether it be clothes, radios, or automobiles? Is it not a good thing that the people in this country as a whole want those things which they own and use to be good looking? Regardless of servicing, a sufficient amount of use of an automobile will cause it to become shabby. It is believed that this factor, together with the desire to keep up with one's neighbors, played a large part in the purchase of new cars by people who were already in possession of cars which should give much more satisfactory service. It is also true that many people like to tinker with their own cars, and perhaps more damage is done by them than by almost any so-called service mechanic.

It would seem a tremendous waste of time and energy if each automobile manufacturer were to undertake the task of adequately training service men for their particular products in each village, town, or city in this country. Undoubtedly all automobile manufacturers, being progressive, will continue to have changes. To undertake the annual return of all automobile mechanics, who are actually in the field servicing popular makes, to the factory and the preparation of material designed to make them understand the technical questions involved as well as the practical would be a task requiring a tremendous investment without accomplishing the desired result. The use of the automobile is so widespread and its influence has been such that it is today a part of the duty of each community to provide the necessary facilities for what it is now believed can be standard auto mechanic instruction.

If the school systems would change their attitude somewhat, so that from the beginning youngsters were not impressed with the idea that the entire purpose of their school education is to fit them so that it will be unnecessary to work in the trades, it would be a big step in this direction. If, in addition to this, work on autos were introduced and available in our schools, the resulting mass effort would soon solve the problem.

The city of Detroit, in the Wilbur Wright High School, has what seems to be the right idea. Here, right on the job, standard makes of cars are brought in, overhauled, and repaired by the students, who at the same time are making themselves scholastically eligible for high-school diplomas. This school is operated on the cooperative plan. The student works two weeks in a garage, service station, or auto factory, and then spends two weeks in the school. The curriculum has been carefully worked out and provides as nearly as possible a connection between the theory taught in the classroom and the work in the plant.

Certainly there is room in the service end of the automobile industry for people in possession of all of the necessary personal traits for attracting instead of repelling customers. Certainly, also, the average percentage of people with these personal characteristics is present either in the blacksmith shop or other repair shop now handling the automobile service work. It would seem that the quickest solution would be to supply these existing service men the supplementary education necessary to develop these personal characteristics. To do this part of the educational job the automobile manufacturer must find some means for supplying these men with the knowledge and information which will be most helpful to them, whether it be along the lines of the development of personal characteristics or of the mechanics of their job. Undoubtedly some means for accomplishing this will be found. The writer believes that it will be along the lines of the present executive training extension work which is being applied to the executives in many of the leading automobile factories.

His thought, then, would be for the community to undertake and set up courses as part of their regular school work. These courses would be open to men selected by the educators and who had a knowledge of the requirements of the automobile industry. The curriculum could be set up in close contact with the industry generally. The industry would then be getting all of the things which the author has advocated, plus a much broader dissemination than would be possible in any single factory or even industry. The responsibility and work would be placed where they belong, in the hands of the educational organization in the community.

MAN-52-7

Summary of the Study of Technical Institutes

By W. E. WICKENDEN,[1] CLEVELAND, OHIO

THIS PAPER presents a highly condensed résumé of a study of a technical education above the secondary level, but of a more intensive and practical type than that offered by the four-year engineering college. The study has not included trade schools which train for skilled crafts, nor junior colleges which give the first half of a complete college course. Only terminal courses have been considered, and in general those which include in addition to technical subjects proper a substantial treatment of underlying sciences and drawing and usually some work in English and economics. The term technical institute appears to be the best common designation for the schools considered. Three rather distinct types of curricula fall within the area of the study: (1) Engineering courses which parallel the college courses in more intensive and practical forms; (2) courses in the technology of specific industries; and (3) courses preparing for particular technical functions. Some apprentice courses in industry are of a post-secondary character and include considerable formal instruction, but it has not been practicable to cover them in this study. Certain correspondence and extension courses have been included, though not comprehensively. Evening courses have been included, where the total ground covered is equivalent to a full academic year or more. In general, the study deals with an area of technical education, rather than a particular type of school.

The broader outlines of the study fell under three heads: (1) A study of typical technical institutes in the United States and of their personnel and courses; (2) a study of the needs of industry which can be met most acceptably through technical education of this character; and (3) a comparison of American and European technical education in this area. The third of these divisions has been presented to this Society in a previous paper and will be referred to but incidentally in the present instance.

Summary of Principal Conclusions

American industry, in practically all its branches, is understaffed with technically educated men; it must look increasingly to the schools rather than to the ranks for its technical and supervisory personnel. Its processes are becoming so specialized that experience, without special organization and supplementary instruction, is of diminishing value as training. Equipment and processes alike are growing constantly more technical, and there is a striking rise in the ratio of staff experts, of supervisors, and of technicians to the total forces employed. Meanwhile boys of superior ability are remaining longer in school—seven times as high a proportion attend high school as 30 years ago—and immigration restrictions have greatly cut down the influx of trained men from abroad.

The situation in industry should be met by a great expansion of higher technical education. Past efforts to meet similar needs have led to a great multiplication and expansion of engineering colleges, giving courses of four years and longer for degrees. Only this one phase of technical education has been adequately provided for in the United States. Greater efficiency demands that technical education should be diversified to meet a wider variety of individual and industrial needs. To maintain but one type of school is to invite blurring of aims and compromise of standards. Progress is in the direction of schools having more definite purposes and more clearly visualized aims.

The present group of engineering colleges, numbering close to 150 and graduating about 9000 men each year, do not provide adequately for the needs of industry. Engineering and sales staffs are fairly well recruited from this source; production and operating staffs most inadequately. Manufacturing industries estimate the desirable ratio of four-year engineering graduates to total forces at from 2.2 to 3.0 per cent. In a few industries this ratio of recruitment is being approached, while in others great deficits exist. Taken as a whole, this potential demand is about one-third supplied. The same industries estimate the desirable ratio of recruits from technical institutes, giving approximately two years of training above the secondary level, at from 6.0 to 8.3 per cent of the total forces. At present this potential demand is not more than one-fiftieth supplied, and an output of 25,000 to 30,000 graduates per year could be absorbed to great advantage. The estimates of relative needs by public-utility and transportation companies are of the same order, and there are grounds for believing that they fairly represent the mineral industries as well.

All the indications, both at home and abroad, point to the conclusion that the needs of the country can be best served by a great expansion in the area of the technical institutes, rather than by a further multiplication of engineering colleges. The colleges have developed around the idea of preparation for distinctly intellectual callings; the technical institutes aim principally at the higher forms of practical pursuits. The supervision of industrial production attracts the smallest proportion of college graduates, among the major functions of industry, and the largest proportion of graduates of technical institutes.

The technical institutes appear to cater more effectively than the engineering colleges to young men who have previously passed through a period of industrial experience and orientation, to men who have a career plan definitely mapped, to men who have passed out of a state of book-mindedness, to men whose natural learning processes center in actual doing rather than formal study, and to men who for financial or other reasons cannot devote four years or more to preparation for remunerative employment.

There is every reason to believe that enrolments in part-time and full-time day technical schools can be greatly increased. So far as total economic production is concerned the need for the labor of young persons is diminishing very rapidly. Great numbers are already partly or wholly free from the burden of self-support until the age of 21. The bent toward technical pursuits normally asserts itself between the ages of 16 and 19, and if higher technical education, in practical as well as theoretical forms, is made widely available locally, great numbers can be attracted to it.

Experience both in America and abroad indicates definitely that the more intensive and practical forms of higher technical education may be expected to achieve permanency and a large success only in institutions which have their own distinctive field and character. Attempts to do this work in auxiliary departments or in short courses of regular engineering colleges have

[1] President, Case School of Applied Science.

Contributed by the Committee on Education and Training for the Industries and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

usually failed. There is as yet no basis in experience for expecting it to succeed in so-called junior colleges, especially those of a mixed character. The junior college is, in reality, an extension of secondary education and its curriculum a truncated college course. The technical institute needs the direction of men intimately in touch with industry and especially proficient in technical education.

Evening technical institutes constitute a strong second line of resources, though one of marked limitations. The full-time day school can ordinarily maintain a rate of progress from four to six times that of the evening school, and the half-time day school on a virtually all-year basis a rate two and one-half to four times that of the evening school. In a few instances evening schools considerably narrow these ratios by careful selection of students and exceptionally intensive work. It is difficult to maintain an efficient staff for evening instruction, unless the school is an auxiliary to a day school or a large industrial establishment. Correspondence and extension courses under private or university auspices are highly valuable expedients where established educational facilities are deficient. A vast field would remain to these agencies, even though a strong technical institute should be established in every industrial center of 50,000 or more inhabitants.

The cooperative plan, based on alternating periods of school work and industrial employment, appears to be particularly well adapted to the aims and levels of work of the technical institutes. This plan eases the economic burden on the school and the student alike. It affords the student a valid trial of aptitude and a normal orientation to industry, without necessitating a break in the continuity of education. This plan seems especially well adapted to the training of supervisory personnel, men who begin in overalls and climb the ladder which rises through foremanship to superintendency, and ultimately to management. It should be pointed out, however, that the cooperative plan does not obviate in any large degree the need for extensive scientific and technical equipment. The demands on equipment in a technical institute are, in fact, fully as intensive as in the engineering college.

The major geographical field of the technical institutes is at present in the dominantly industrial area east of the Mississippi and north of the Ohio and Potomac rivers. There is little immediate prospects of a local demand for schools of this character in the dominantly agricultural areas. It seems probable that institutes of a monotechnic type could be sustained successfully in the more intensively developed mining areas. The place of the independent endowed technical institute resembles that of the endowed college or university in many respects. It has been almost a rule in American experience that private initiative has been quicker to recognize neglected areas of education and to occupy them with pioneer institutions than have the public authorities. At a later stage, when the need has been advertised and examples of successful effort have gained some prominence, the public steps in and provides for the greater part of the need. The independent schools are still able to capitalize their freedom for experimentation with curricula, teaching methods, and selective standards of admission and to uphold an ideal of special excellence rather than large enrolments.

The private proprietary institution has been able to maintain itself in this field, because of otherwise unsatisfied demands, and in certain instances has rendered an admirable service at an economical cost. Doubtless there will always be a place for highly distinctive schools of this character. Welfare organizations have also entered the field, with the aim of serving men not provided for by other educational agencies. As a rule, these organizations have been under the necessity of making their educational activities pay their way in full, and the limited resources and equipment have left room for doubt as to the quality and permanence of their work, once the public awakens to its responsibility. A number of corporation schools which serve as means of selective recruitment and training for special types of personnel have gained an apparently permanent status.

The actual needs and potential demands, however, are beyond the resources of voluntary or private agencies. The situation seems to call for a great chain of community institutions, with their organic place in city and state educational systems. The author's view is that these schools should have a distinct character and a definitely technical program of work and that they should be set apart from the present system of comprehensive secondary schools and junior colleges. These institutions would provide both day and evening instruction. The author sees no necessity for limiting it to the field of post-secondary education which is the subject of the present study; secondary courses, with well-defined technical objectives, might well be included, as well as short unit courses for men with more limited needs. There are, in fact, a number of technical high schools for boys, which could be extended so as to do effective work in the post-secondary field and in real liaison with industry.

It would not be practicable to establish municipal technical institutes in the smaller cities. If this gap is to be well filled, it must be done by the states. The state, it would seem, should take the responsibility for training men for the more decentralized vocations, such as horology, which would only rarely fall within the scope of city institutions. The author believes that the largest field to be served is that of training in the technology of industries rather than that of generalized engineering courses. The former is largely neglected by the colleges and the latter widely and fairly adequately covered. This estimate of relative needs, however, does not reflect upon the effectiveness of the engineering courses of the technical institutes, some of which are of great excellence. The textile school, the foundry school, the machine production school, the building construction school, the printing and engraving school, and the leather industries school, however, are types in great need of multiplication.

Typical Schools and Programs

The technical institutes have such a high degree of individuality that it is almost impossible to exhibit their salient features in a small compass. Two general types are represented in the accompanying tables, the first (Table 1) a group of six full-time schools of well-established character, and the second (Table 2) a group of schools giving only evening courses in the realm of this study.

All of the institutions listed in Table 1 are independent of public support, and all but the first two are well endowed. All provide scholarship aid for a limited number of deserving students and assist some others by loans or employment. None, however, have scholarships to assist their graduates in pursuing further studies. Bliss alone of this group has dormitories and a required residential system. All but the Chicago Technical College have alumni organizations. Pratt and Rochester report some influence from employers favoring a change to college degree courses, and four schools report similar pressure to a minor degree from graduates and faculty members. Graduates of four schools in the group express some desire for more advanced courses. There is little active demand for other courses comparable to those now given, but such courses would probably be welcomed if offered. The heads of four institutions believe that education of this character can be given best in separate institutions; four designate full-time day courses as the best plan; one head prefers cooperative day courses; and the others rank this plan as "fair" to "good." None of the group prefers a sequence of one-year unit courses.

TABLE 1 FULL-TIME AND COOPERATIVE TECHNICAL INSTITUTES

	Bliss Electrical School	Chicago Technical College	Ohio Mechanics Institute	Pratt Institute	Rochester Mechanics Institute	Wentworth Institute
Names of courses	Electrical engineering	Architecture; building construction; civil, electrical, and mechanical engineering	Industrial electrical, mechanical, and industrial engineering; cooperative power laundry course	Industrial mechanical, electrical, and chemical engineering	Cooperative electrical, mechanical, chemical	Machine construction; electrical construction; power plant; architectural construction; foundry
Length in years	1	2	2	2	3	2
Weeks attendance per year	32	36	36 (engineering) 21[b] (laundry)	36	19[b]	36
Hours attendance per week	35	36	32½	30		30
Hours home-work per week	15	20	12 to 15	21		15
Entrance Requirements:

TABLE 2 EVENING TECHNICAL INSTITUTES AND EXTENSION SCHOOLS

	Cleveland Y-Tech.	Newark Technical School	Westinghouse Technical School	Rutgers University Extension	Penn State College Extension
Names of courses	Mechanical, electrical, structural, and chemical junior college	Civil, architectural, mechanical, electrical, automotive, and chemical engineering	Engineering	Essentials of mechanical engineering	Engineering
Length in years	3	4	4	3	3
Weeks attendance per year	40	28	32	24 to 26	24
Hours attendance per week	9	10 to 13	9	5	5
Hours home-work per week	12	4	9	5	5
Entrance requirements:					
Minimum age	None	16	None	18	None
Education	High school	High school or special preparatory course	2 years high school minimum	1 year algebra and service or equivalent	8th grade
Industrial experience	No definite requirement; average 3 years	None required; 3 years preferred	None required; students are employees	None required	Not required; 1 year or more preferred
Enrolment, February, 1928	[a]	1440	272	104	592
Graduates, 1927–28	4[a]	100	32	7[a]	95
Students dropped, 1927–28	46	260	82	8[a]	121
Tuition per year	$126	$60	$52	$40–$45	$30
Cost of instruction per student		$80	$58	$60–$67	$44.40
Plant and equipment provided	Gifts and earnings	Public and gifts	Rental, earnings, and gifts	State	State

[a] Course newly established.

Of the schools referred to in Table 2, only Westinghouse has scholarships and relatively few of them. Scholarship aid is usually regarded as unnecessary for evening students, practically all of whom are employed. Newark alone has scholarships to aid graduates in pursuing further studies. All but Cleveland Y-Tech. have alumni organizations. Employers apparently exert no effort to have the courses changed to a degree basis, but graduates do to a minor degree in two institutions. Graduates frequently ask for opportunities to go on with more advanced and specialized courses. Demands for additional courses comparable to those now given are not active, but might be cultivated, in the opinion of the directors.

Students and Student Life

The technical institutes do not, as a rule, insist on graduation from a four-year high school as a basis for admission. The percentage of high-school graduates runs high, however, in the more efficient day schools, less in the established evening schools, and low in the extension evening schools. The range is from a maximum of 95 per cent in the first group to a minimum of 36 per cent in the third. While few technical institutes make a formal requirement of industrial experience before entrance, nearly all prefer it. The number of entrants having had such experience ranges from 43 per cent in a day textile school, as a minimum, to 95 per cent in an established evening school, as a maximum. In this respect the evening schools as a group rank highest, the extension schools second, and the day schools lowest, as might be expected. In general, however, the previous employment in a majority of cases appears not to have been of a highly technical nature. The median ages of student groups, by schools, range from 19 years and 8 months to 25 years and 2 months, with a general median of all groups of 21 years and 0 months. Evidently students on completing their studies are mature enough to take on responsibilities and not too old or too highly individualized to fit into producing organizations. Few students are sons of professional men; the largest group, or about one-half of the whole, are sons of industrial employees.

Information given by alumni indicates that fully two-thirds of the students enter the technical institutes with a specific field of work in view. The chief reasons for this preference are given as special ability (39 per cent), being employed at it (31 per cent), economic possibilities (16 per cent), and family or personal influences (11 per cent).

Evidence gathered from nearly 1350 students and 600 alumni of a group of eight schools makes it clear that certain well-defined influences govern the choice of a school and a course of study. These may be classified as given at the top of page 66.

The most significant inference, it seems, is that so large a proportion deliberately decide to seek further education and choose a school by its reputation and a program of work suited to their time and means. Personal guidance by parents and others is apparently a minor, though growing, factor. Data

Influences Which Govern the Choice of School and Course

	Alumni		Present students	
	Yes, %	No, %	Yes, %	No, %
Believing personally in this type of education	84	16	90	10
Reputation of the particular school	75	25	85	15
Personal realization of need from practical experience	71	29	77	23
Lack of means for a long course of study	71	29	63	37
Knowing or knowing of successful alumni	53	47	66	34
Suggestions of friends	49	51	61	39
Lack of time for a long course	50	50	51	49
Institution being near home	38	62	37	63
Advice of alumni	37	63	44	56
Incomplete preparation for college entrance	39	61	33	67
Desire of parents	21	79	35	65
Advice of teachers in previous schools	14	86	30	70
Recommendation of employer	14	86	23	77
Desire for a particular section of the country	13	87	14	86
Advertisements of the school	14	86	11	89
Solicitation by person or correspondence	6	94	12	88

gathered from students in eight additional institutions corroborate these findings quite consistently.

Many other facts, gathered chiefly from alumni, throw light on student life and experience. Most of the technical institutes cultivate an active student life through athletics, clubs, social activities, and the like, though on a less elaborate scale than in the colleges. Participation in these activities appears to be quite general, 44 per cent of those replying specifying athletics, 36 per cent clubs and societies, 31 per cent school or class organizations, 16 per cent publications, and only 19 per cent no extra-curricular activities. The proportion who paid a considerable part of their own way is fairly striking: Earning no part, 17 per cent; to one-quarter, 16 per cent; from one-quarter to one-half, 14 per cent; from one-half to three-quarters, 11 per cent; from three-quarters to all, 42 per cent. Of those earning part or all of their own way, 32 per cent did so before entrance, 25 per cent in summer, 24 per cent during the school year, 17 per cent borrowed funds, and 2 per cent dropped out and later returned. This large measure of self-support doubtless accounts for the independent choices of schools and courses and contributes to the earnest, eager spirit so generally manifested by the student bodies.

Teachers and Teaching

Ten institutions were studied under this head. It is evident from the data that formal academic qualifications are not the primary criterion in the choice of teachers. One-fifth of the entire group of teachers are not high-school graduates, but every teacher has had training beyond the high school; more than 70 per cent of the teachers have had four years or more of such training and 18 per cent have had one year or more of post-graduate university work. The emphasis on the college degree varies widely. In one of the most efficient schools 12 of the 14 instructors do not hold degrees, but are graduates of the school itself. On the other hand all the instructors in two of the ten schools hold degrees. In general a considerable number of the teachers are themselves the product of some form of adult education.

While formal academic credentials are not highly emphasized, great weight is given to active industrial experience. Fully 97 per cent of the teachers reporting have had a year or more of non-teaching experience, obtained in most cases before entering their present work. Of this number more than half have had five years or more of experience in practice. Many teachers in evening and extension schools are in active practice in their professions, while those in full-time schools usually maintain a fair degree of collateral practice. Over 60 per cent of the teachers are enrolled in one or more professional societies. The amount of original productive work is considerable, more than one-quarter of the teachers having publications to their credit and one-fifth having made one or more inventions.

One-quarter of the teachers are under 30 years of age and less than one-tenth are above 50 years. The median age is close to 35 and the median period of teaching experience is about 7.5 years. Lack of common units or comparable conditions makes it difficult to give an accurate picture of teaching loads. In general, the loads in full-time schools run higher in clock hours than in the colleges; namely, from 18 to 35 per week. Class sections are frequently fairly large, numbering from 35 to 40 men, and laboratory, drawing, and shop sections from 15 to 25 men. Where both day and evening classes are held, teachers commonly have part of their work in each division.

The subjects taught by one instructor are along closely related departmental lines, as a rule. The coordination between departments or individuals varies even more widely than in the colleges. Wherever a highly distinctive course has been developed, the work of individual instructors is close-knit; at the other extreme instructors confess to being "uncertain" of their responsibilities and go by their own judgment as long as no one objects. In a few schools the materials of teaching are closely scrutinized by a committee of the faculty, and cooperation between departments is secured by frequent conferences. Special manuals of instruction, prepared by the local staff, are used in the majority of classes. Local needs are usually conceived to be unique; frequent comment that "no published material suits our situation" is met. A bare beginning has been made in providing published texts with this field of teaching in view. When one considers the stereotyping influence of the textbook in the engineering colleges, he hopes that the technical institutes may be able to maintain conditions that favor greater originality and flexibility. On the other hand, the present lack of prepared teaching materials undoubtedly tends to check the spread of the much-needed types of schools and courses.

Teaching methods in the technical institutes do not depart widely from accepted practices. In general, however, the theoretical phases are greatly condensed and the practical phases more heavily stressed. Some teachers state that they test and grade their pupils by their ability to make practical applications of their studies. It appears that in many cases a higher proportion of the student's work is done in scheduled hours under supervision than in more academic types of schools; nearly half the teachers, in fact, report that from two-thirds to all of their work is of this type. The assigned work to be done outside, as a rule, consists less of text material than of problems and exercises. Nearly half of the teachers report basing less than one-third of their assignments on text materials. While it is not explicitly stated in any of the reports, it appears that the technical institutes cater to "learners" rather than "students."

No great originality of method has been observed. One institution emphasizes that fact that the practical work given in the first year is a foundation for the theoretical work of the second; another that its teaching matter is selected in the light of job analysis; while in two cases the courses are divided into well-defined units, with practical exercises closely paralleling the text material to enable students to enter at any time, progress at an individual pace, leave when they wish, and resume the program at any point. In general, the lecture is but little favored. Conferences and recitations, with active participation, make up the greater part of the classroom activity. Drawing, shop, and laboratory exercises are largely stressed. In textile schools the instruction matters are very specific, all general studies being eliminated. The heads of all schools agree in emphasizing the practical qualities of their instruction, pointed directly to employment objectives and dealing with specific problems which their graduates will meet in industrial work. There is little tangible evidence, however, that practical performance is given great weight in grading their classroom performance. Aside from two schools with cooperative courses,

only one makes industrial experience a definite prerequisite for admission or for graduation.

The off-campus teaching of the state college extension divisions, as observed, was distinctly below that of the regularly organized technical institutes in efficiency. The classes were less homogeneous in ability and preparation; practical equipment was almost wholly lacking; and teaching is apparently a "pick-up" task for part-time men without training in educational methods and with little time for planning and preparation. The extension enterprise, while of undoubted value where other facilities are lacking, appears to have many of the qualities of a business, to be expended with only minor concern for admission standards, vocational selection, teaching efficiency, and the like. It is possible that these efforts may actually retard rather than advance efficient state-wide programs of technical education of a non-college type, in order to preempt financial support and control for the benefit of a state college or university.

In the matter of teaching salaries no common basis exists for a comparison of full-time and part-time staffs. Data covering three full-time staffs exemplifying the best standards cover a range of individual salaries from $1900 to $6000 per annum with medians of $3600, $3100, and $3000, respectively. The rates for evening teaching alone are in some cases proportionate to these scales, but in most cases very much less. In fact much evening teaching is plainly a means of earning extra income adopted by low-salaried men in practice, though some notably successful teachers are to be found in this group. But one individual reported a normal salary in excess of $5000, and the modal group lies between $2500 and $3500. Data on earned incomes from outside practice for the three full-time staffs cited show a range of from nothing to $10,000 per year. Apparently about half of the combined groups enjoy an appreciable supplementary income, although most schools encourage a reasonable amount of outside work.

Speaking out of their own experience, the teachers emphasize the following as their most important qualifications, in the order stated:

(1) Knowledge of the subject
(2) Experience in practice
(3) Ability to present the subject clearly
(4) Ability to inspire interest in the student
(5) Understanding of relations with industry
(6) Sympathetic insight into the student's individual problems.

The organization of the ten schools studied provides in general for greater centralization of authority than is common in college faculties. Only three of these faculties are organized, although all meet occasionally in an advisory capacity. The directors usually select the teachers. Few of them report exceptional difficulties in finding men, although one of the most discriminating directors reports that neither ex-college teachers nor mature men from industry, as a rule, have been found satisfactory. All but two of the schools draw from industry more than from other sources. Four definitely prefer their own alumni; the others in only a minority of their appointments.

Status of Graduates

It has been seen that chance is only a minor factor in the choice of a school and a course of study. The same is true of a choice of position after graduation. The main reasons assigned by graduates are as follows: Special interest, 35.8 per cent; special ability 8.7 per cent; future economic possibility, 10.2 per cent; present economic advantage, 6.5 per cent; geographic location, 6.9 per cent; family influence or connections, 6.4 per cent; only position available, 19.4 per cent; other reasons, 6.1 per cent. There is considerable shifting of employment in the first few years after graduation. Graduates of five technical institutes were studied and compared with graduates of engineering colleges. The variations among the five groups were not marked and the composite result is fairly representative.

Percentage of Graduates Holding Indicated Number of Positions in Certain Periods

	—Technical institutes—				Engineering colleges		
Number of Positions	One	Two	Three	Four	One	Two	Three
Period:							
6 months	91.2	7.8	1.0	...	79.7	20.3	...
18 months	57.3	30.1	11.6	1.0	60.5	26.5	13.0
30 months	25.7	46.6	20.8	6.9	43.0	32.0	25.0

In general there is a fairly close agreement between the fields of work of graduates and the courses of training pursued. Variations between schools are relatively small, and the composite result is therefore representative. Comparisons with engineering graduates are of interest.

Percentages of Graduates in Fields of Work as Related to Courses

	Same as course	Closely allied	Not closely allied
Technical institute	69.8	17.9	12.3
Engineering course	61.8	7.4	30.0

The closer relation in the former case sustains the view that men attend technical institutes with more definite aims in view than those of engineering college students. It is difficult, in small compass, to indicate the specific character of the positions held or the routes of progress along which graduates advance. The three largest groups are: (1) Supervisors (production, operation, maintenance, etc.), (2) engineering personnel, and (3) proprietors of businesses. About two-thirds are included under these heads.

Employers of graduates have listed the more outstanding traits or types of adaptability of technical institute graduates in the following order:

1 Adaptable to supervisory positions and advancement in operating departments
2 Adaptable to plant operation and maintenance
3 Ability to get on with workmen
4 Adaptable to technical services (drafting, designing, editing, testing, inspection, etc.)
5 Ability to do team work with associates
6 Ability to cooperate with executives
7 Adaptable to construction and erection in the field
8 Willingness to accept plant hours and conditions of work
9 Adaptable to technical sales work

The ratings of employers were equally divided between *yes* and *no* on the two items:

10 Adaptability to administrative or executive positions
11 Adaptability to technical forms of business, such as contracting

The opinions were distinctly negative on the two following items:

12 Adaptability to staff engineering positions
13 Reasonable expectations of advancement in salary and rank.

It should be noted, however, that considerable variations exist between schools in the rating of graduates. Graduates of one of the strongest schools, with a definite engineering emphasis, were rated as "better than average," tending toward "outstanding" on adaptability to staff engineering positions, and even higher on adaptability to technical sales work.

The earning power of graduates of the more thoroughly organized and efficient technical institutes parallels that of engineering college graduates of the same maturity. The differential

between the medians of the two groups is not large in any case, and scarcely any exists between the more carefully selected graduates of technical institutes and college graduates in general. As an illustration a comparison may be made between the medians of four groups: (1) Engineering college graduates in general; (2) four-year electrical engineering graduates of a somewhat selected character; (3) two-year electrical engineering graduates from one of the outstanding technical institutes; and (4) one-year electrical engineering graduates from a school of excellent quality:

Comparison of Median Earnings of Graduates

Years after graduation	0	2	4	10	15
Four-year graduates in general	$1500	$2100	$2600	$4000	$5000
Four-year graduates in electrical engineering	1500	1900	2460	4000	4850
Two-year graduates in electrical engineering	1450	1800	2450	3350	4700
One-year graduates in electrical engineering	1200	1600	2050	3100	4600

The institutes experience no difficulty in placing their graduates once the product is tried and known. The contacts with employers in nearby areas are usually close, and a few schools have made permanent contacts with employers in more distant sections. For example, one has a standing order from a large concern for five graduates each year, who are accepted without interview on the judgment of the officers of the school. Institutes operating on the cooperative plan have no employment problems of consequence, but experience a demand from their clientele greater than their supply.

Reactions of Graduates to Their Education

A valuable index to the effectiveness of a particular type of education is found in the reactions of graduates. The alumni of eight schools were questioned, and the results show only minor variations between institutions. The composite replies were as follows:

To what extent has the course met your expectations:	Good, %	Fair, %	Poor, %
(1) In satisfying the technical requirements of your job?	75.5	22.8	1.7
(2) In satisfying supervisory, managerial, or other requirements?	48.2	40.0	11.8
(3) In your earning capacity?	41.1	50.7	8.2
(4) In your general education?	52.3	40.3	7.4
	Yes, %	No, %	Blank, %
Have you felt the need or desire for further courses of study?	81.9	8.2	9.9
Have you had any extension or correspondence courses?	34.8	40.6	24.6

The reasons offered for needing further courses were as follows: Fuller general knowledge (36.1%), continuing more advanced work (28.6%), broader business knowledge (27.9%), making up deficiencies (3.9%), greater responsibility (3.5%).

The suggestions offered for changes in the technical institute courses may be ranked in the following order: English and public speaking (29.7%), more and higher mathematics (29.1%), commercial and business subjects (17.0), more science (13.3%), practical applications (4.9%), cultural subjects (3.6%), miscellaneous (2.4%). The desire for a broader and more fundamental education is clearly revealed.

The replies to the question as to whether graduates of technical institutes would do it over again are of special significance:

If you had it to do over again, would you:	Yes, %	No, %
Go to the same type of school?	88.9	11.1
Take the same course?	84.4	15.6
Go to another type of school, such as the four-year college?	80.1	19.9

The apparent inconsistency in the first and third items is easily explained by assuming that the words "under the same circumstances" are understood in the first case.

Testimony as to any tangible handicaps resulting from the absence of a college degree is as follows:

	Yes, %	No, %
(1) In obtaining employment?	20	80
(2) In obtaining advancement?	24	76
(3) In gaining recognition by professional and business organizations	29	71

There is apparent need of recognition or credentials of broader acceptance, but it seems clearly not to be in the form of meaningless degrees. The desire for degrees was manifested almost wholly by those recently graduated.

Technical Training Needs of Industry

Of all the evidence gathered that which deals with the requirements of industry is probably the most conclusive. The State of New Jersey was selected for an intensive study of the needs of industry for technically trained men. A number of reasons contributed to this choice, including the existence of considerable data, the diversity of industries, proximity to the base of studies, and familiarity of employers with the technical institute graduate. Three separate inquiries were made, with startingly consistent results.

Quotas of Graduates of Technical Institutes and Engineering College Graduates Preferred by 48 Manufacturing Companies[a]

Field of employment	Technical institute men	Four-year college men or beyond
Mechanical	817	316
Electrical	116	111
Civil engineering	6	18
Chemical	345	146
Mining	6	4
Miscellaneous	12	0
Total	1302	595
Ratio	2.8 to	1

[a] Data from survey of Rutgers University by U. S. Bureau of Education.

The second inquiry was made by the Dean of Engineering at Rutgers independently. Data came from 21 manufacturing companies, representing a wide range of industries.

Ratios of Technically Trained Graduates Desired by 21 Manufacturing Companies

	Four-year college	Technical institute	Manual and crafts
Percentage of total employees	2.2	6.0	14.8
Ratios	1 to	2.7 to	6.7

The third study was made by a large and comprehensive public utility organization covering the same area, in cooperation with the staff.

Ratio of Technical Institute Graduates to Four-Year College Men Desired by a Large Public Utility Organization

	Technical institute	Four-year college
Percentage of total employees	8.3	3.1
Ratio	2.7 to	1

A fourth study, made in California by Frank W. Thomas, quite independently, gave the number of positions in twelve corporations which were believed to require only two years of "college work" as 755, and the number believed to require four years of "college work" as 289, or a ratio of 2.6 to 1.

In order to check the results obtained from so local an area as New Jersey, an inquiry was made of 15 representative companies in 11 states which were believed to have had considerable experience with both college and technical institute graduates. It was found that 12 had had considerable experience as anticipated, two some experience, and one not enough to justify an expression. These companies were asked whether from their experience they felt that there was an area of terminal technical education, intermediate in duration between vocational and trade schools on the one hand and engineering colleges on the other, needing to be encouraged and developed in America. The replies were unanimous in the affirmative. The relative

importance of the aims of technical institute training, as indicated by the composite replies of these 15 companies, was as follows:

Aims of Technical Institute Education	Weights
(1) To qualify men for supervisory positions in operating departments	1.00
(2) To qualify for technical services such as drafting, designing, testing, inspection, etc	0.74
(3) To qualify for commercial positions relating to the sale of technical products and services	0.56

In reply to a query whether they would prefer men graduated from a *general* course covering a fairly wide field of study and intended to qualify men for a wide variety of work, or from a *specialized* course covering intensively a particular line, the result was seven in favor of the specialized course, five for the general, and the others non-committal. The value of both types was generally recognized.

Through the courtesy of the National Industrial Conference Board, data were obtained on the personnel of the more important technical and supervisory positions in 878 concerns employing 429,600 men in five major manufacturing industries. The distribution of the college-trained men in the major groups of positions or functions in these companies are as shown below:

Percentages of Technical and Supervisory Positions in Manufacturing Now Held by College Trained Men

Groups of positions	Chemical industry	Electrical manufacturing	Metal trades	Paper and pulp	Rubber industry	Total of the five industries
General officers	65.0	47.1	45.8	32.8	43.9	46.6
Engineering and technical	57.2	55.2	31.0	50.4	55.2	48.6
Production	17.6	10.3	5.6	10.4	9.4	9.3
Sales	23.4	58.7	24.5	15.3	19.3	38.4
Miscellaneous	11.6	19.1	7.7	9.5	23.5	13.8
For the industry	29.8	37.1	17.1	22.0	23.8	28.0

The relatively low recruitment of production officers from college sources cannot escape attention.

In the following tabulation a comparison is made of two groups of college graduates and of six groups of technical institute graduates with respect to functions in industry:

	Groups of positions				
	Miscellaneous, %	General officers, %	Engineering and technical, %	Sales and advertising, %	Production, %
College, 3199 non-engineering graduates	18.4	20.1	10.3	42.1	9.1
College, 11,895 engineering graduates	7.7	7.2	39.2	36.9	9.0
Lowell Textile Institute, 325 three-year graduates	23.1	22.5	20.0	10.1	24.3
Pratt Institute, 1176 two-year mechanical engineering	9.0	17.9	41.9	9.6	21.6
Pratt Institute, 656 two-year chemical engineering	5.5	17.2	42.7	9.0	25.6
Pratt Institute, 1187 two-year electrical engineering	7.8	11.9	40.6	9.3	30.4
Bliss Electrical School, 1398 one-year electrical	23.8	11.1	26.0	6.1	33.0
Wentworth Institute, 377 two-year various	15.7	4.8	32.3	8.7	38.5

Estimate of Total Potential Requirements

Estimates of the total potential requirements for technical institute training are likely to be conservative if one is concerned chiefly to guarantee a maximum individual opportunity to those so trained, or liberal if one is guided by the estimates of the personnel needs of employers. No data exist for estimates of the former type. As a basis for the latter, there is the expressed opinion of manufacturers and others covering the desired ratios of various types of trained personnel to total forces and to each other. Applying these ratios to the manufacturing industries of the country at large gives results as follows:

Total employees in manufacturing (1925)	9,857,697
Approximate technical institute graduates employed	10,000
Approximate total of technical institute graduates desired	591,462
Annual quota of technical institute graduates at 3 per cent	17,745
Annual quota of technical institute graduates at 5 per cent	29,573

If an estimate is made for the mineral extraction industries by assuming that like ratios may be applied to the salaried officers as to the technical and supervisory of the manufacturing industries, the result is as follows:

Total salaried officers in mineral extraction	96,115
Estimated number of college graduates needed	13,404
Estimated number of technical institute graduates needed	36,191
Estimated number from the ranks and otherwise trained	46,520
Annual quota of technical institute graduates at 3 per cent	1,086
Annual quota of technical institute graduates at 5 per cent	1,810

A study of the personnel needs in transportation and communication has indicated that a proportional total of technical institute graduates would be 100,000, or an annual quota of 3000 at 3 per cent or 5000 at 5 per cent. When additional allowances are made for other census classifications, such as agriculture, forestry, personal service, trade, professional service, and clerical occupations, the total annual quotas to maintain an optimum recruitment of industry, in its all-inclusive sense, work out at approximately 36,000 at 3 per cent of the total appropriate positions and 50,000 at 5 per cent of the total appropriate positions.

In fact, the potential fields for employment of technical institute graduates appear to be limited only by the sources and facilities to train them and the right kind of men to be trained.

Discussion

James A. Moyer.[2] This paper must necessarily be merely an abstract of the report of the committee which has been engaged with its experts during the last two years in a survey of the field of technical education as it relates to non-collegiate institutions. Much discussion has arisen as to nomenclature in defining the scope and in recording the results of the survey. The most suitable name for the type of institution to be surveyed was not easily decided. The committee is fairly well agreed, however, that the name non-collegiate is properly descriptive and suitable for the purposes in mind, and yet this name does not properly eliminate from consideration the ordinary vocational or trade school devoted to training of the apprentice grade.

During the period of its existence, the committee and its experts have been devoting much time and thought to the problem to finding out the real field of usefulness of the non-collegiate type of technical institute or school. Unfortunately, there has been a general impression among engineering teachers that there was no well-defined place among our educational institutions for this non-collegiate type. In fact, instructors in search of positions have often hesitated to accept teaching appointments in these institutions because of the unfortunate idea that their work could not be put on a sufficiently high plane. In other words, they did not realize the difference between the educational activity of the type of institution which is being discussed and the ordinary vocational or trade school which is usually supported by taxation.

It occurs frequently that educational institutions for technical training which were originally of the non-collegiate type are being gradually transformed into another more standardized kind, which is called the collegiate type. For more or less personal reasons in some cases the presidents and other executive officers of the non-collegiate type of institution have exerted forcibly their influence for the change, and the facilities of the institutions have invariably given encouragement for very much the same reasons that influenced the executive officers.

There is a striking case which comes to mind in the change from the non-collegiate to the collegiate type of institution in a city in the East. It happened that the institution was founded and

[2] Director, State Department of University Extension, Boston, Mass. Mem. A.S.M.E.

had for its first president a man who realized the important work which could be done by a non-collegiate type of institution, and who was not carried away from a well-defined purpose by a desire for collegiate degrees and academic distinctions. In later years, one of his successors managed to build up the collegiate type of faculty for the institution, and worked year in and year out with the active support of most of his faculty for a change to the collegiate type of institution. Finally, the trustees agreed to adopt his recommendations, and now there is one more collegiate type of technical institution almost within a stone's throw of another long-established and increasingly useful college of engineering. In this case, there is no doubt that the institution in which the change was made was needed much more in the non-collegiate than in the collegiate field. The difficulty was, however, that the president, the executive officers, and many of the faculty had personal ambitions to be satisfied. Frankly, they did not like being connected with an institution which did not have the highest collegiate standing. Personal academic distinction appeared to be a more important factor with these men than the usefulness of their institution to the community. It was for this reason that they influenced the trustees, with much hesitation on the part of many of them, to make the necessary changes in the admission requirements and in the curriculum, to make a place for the institution among those granting academic degrees and having collegiate standards.

One of the most important conclusions to be drawn from the survey is that the employing agencies of large industrial plants and organizations are able to state with considerable definiteness for what type of employment they prefer the graduate of the non-collegiate technical school. This is especially true in the field of production engineering, where the statistics seem to show that the graduates of the non-collegiate institution have the preference, and will probably be most successful. In fact, the opportunities in this branch of engineering seem to be especially advantageous for the graduates of the non-collegiate institutions. Financial rewards are not lacking for those who are engaged in production departments, and the prospects for advancement to superintendent or head of a department are excellent.

In general, the results of the survey will give renewed enthusiasm to the executive officers and faculties of the non-collegiate type of institution to continue their work in their present fields, and resist the tendency to drag their institution into the collegiate list.

S. S. Edmands.[3] An outstanding feature of this exceedingly valuable and noteworthy paper by an eminent student of higher technical and engineering education is the two-fold conclusion appearing therein; namely, (1) that American industry is understaffed with technically educated men, and (2) that the needs of the country may best be served, not by a further multiplication of engineering colleges, but rather by a great expansion of "technical institutes," an allied type of school to which a large and distinct field of serviceability is assigned. This conclusion is not that of the paper's author alone, but is one of a number of very significant findings in a recently ended comprehensive survey under the auspices of the Society for the Promotion of Engineering Education, with which investigation Doctor Wickenden was associated in the capacity of director.

The diagnosis that American industry is lacking in technically trained personnel will surprise no one conversant with the actual situation, but the prescription of many more trained men from the thus-far few, underdeveloped, and but little-known or understood technical institutes, rather than from the numerous and strong colleges of engineering, would seem quite absurd to the average person, were the pronouncement from almost any source other than the above-mentioned society, which is the foremost champion of the widespread and deservedly well-esteemed college form of technical education. The diagnosis and prescription reflect both the competent character of the investigation and the fairness and broadmindedness of its auspices. The finding is the more impressive because the society's membership is representative chiefly of the American college of engineering and its vast vested interests. However, the motive here should not be mistaken for mere altruism, inasmuch as one of the major conclusions of the society's investigations is that the welfare of the engineering college and the possibilities for continued betterment of its service hinge importantly upon the proper development at the same time of the neglected institute form of higher technical education. The investigations also bring out prominently the fact that no such disparity between the two types of education exists in any other large industrial country, and that the condition contrasts regrettably with the well-balanced systems of technical education maintained by the leading European nations.

This authoritative pronouncement that national lopsidedness in technical education needs correction brings timely reinforcement to the unfortunately few pioneer technical institutes. These have found themselves seriously handicapped in their efforts to make headway against a prevalent national indifference ascribable in part to the general over-emphasis upon the college form of education, and in part also to the long period of unparalleled industrial prosperity that has undoubtedly tended to distract attention from the importance of greater efficiency in American higher technical education. Doctor Wickenden's paper and the study which it so ably summarized should help greatly to stimulate a wider interest in technical education outside of the colleges through dissemination of reliable information regarding the need for and the various service possibilities of the "technical institute."

Walter B. Russell.[4] In presenting this paper the author has rendered a most valuable service both to education and industry. He has helped to crystallize the term "technical institute" as the most suitable name by which to designate schools of the type described. Few persons realize the importance of an appropriate title for any enterprise, especially for a school in a new field which must be clearly understood by people generally, and which, more than most endeavors, needs to have its aims and purposes clear and definite in the public mind. Consequently, one cannot overemphasize the value of this first contribution to the field of education in establishing the general recognition of the name of "technical institute." Clearly these schools were not colleges, nor universities, nor high schools, nor trade schools, nor manual-training schools. Too often in the past it has been necessary to describe them in negative terms, stating what they were not and calling them non-collegiate, non-standardized, etc. By placing emphasis on the name, "technical institute," the author gives these schools a definite place in the educational scheme of the United States. Both the schools and the many thousands of creditable graduates throughout the country welcome the change and rejoice in a new and recognized status.

The next outstanding feature of the study is in the tabulated results of the needs and the potential needs of industry. No one has heretofore known even approximately the extent of the needs of industry for men trained in short, intensive courses of specific character such as those offered by technical institutes. No one has attempted to list the rapidly increasing number of new positions which have developed in production and operating companies, or the range and variety of the new stations and func-

[3] Director, School of Science and Technology, Pratt Institute, Brooklyn, N. Y. Mem. A.S.M.E.

[4] Director, Franklin Union, Boston, Mass. Mem. A.S.M.E.

tions of a supervisory nature which are best filled by men with the technical-institute point of view, the technical-institute orientation, and the technical-institute intensity and definiteness of training. Previous estimates that industry could absorb ten times the number at present graduated are dwarfed by the author's announcement that the potential demand of the industries for this type of graduate with this sort of training is not more than one-fiftieth supplied at the present time. The paper shows the increasing necessity and the general demand for great additions to the numbers of technically trained men who are needed if the industries are to keep pace with the rapid changes which are taking place in organization, in development of new processes, and in the multiplied scale of production.

The field from which the technical institutes draw their students is distinct and separate from that of other kinds of technical training. It is almost as large as the combined fields of all the other more familiar types of education put together. This is made evident by plotting on a chart that shows the population of the United States at each age level between the ages of 5 and 26 years a curve separating those persons who are in school from those out of school. There will be found twenty-five million persons between these ages in school, and almost as many, twenty-three million, over 14 years of age, outside of school. It is this group of twenty-three million between 14 and 26 years of age out of school in "No-Man's-Land" that constitutes the field from which the technical institutes draw their students. There is, therefore, no competition with the standardized or academic forms of training. It is this enormous group of out-of-school youth that must provide the bulk of the supervisors, inspectors, and minor executives so much needed by industry, and who are, according to the author, but one-fiftieth supplied. It is for this vast group of young people who are "off trail" that the technical institutes have established new avenues of training. For various reasons those in this area have left school, and cannot, if they would, get back again into step with the regular program of high school and college. Other trails must be provided if they are to climb in our present industrial life and development.

The technical institutes have but recently started. They are pioneers exploring a new field. The field is almost unlimited. It contains boys and men with an innumerable number of different needs and an endless variety of educational and industrial background. To meet just a few of the most outstanding of the varied requirements of this vast, ungraded group, new types of training have been devised adapted to the new field. With divergent aims and an extraordinary range of talent, each individual requires different treatment, new methods must be employed, original types of training must be evolved, and flexibility of procedure and program provided. Mass instruction has no place here. From start to finish it is special treatment for special needs. The author has called attention to the success which has attended technical institutes, to their work in this zone of education, and to the pioneer quality of their instruction which is being adapted to create new pathways along which young men and women in "No-Man's-Land" may rise to stations of usefulness and importance in industry and in citizenship.

A. L. Williston.[5] The author has done not only this society and the whole engineering profession to whom he makes this report, but also American industry and the cause of sound education everywhere, a service that one cannot easily over-estimate. A few of the more outstanding features of the study that are described in the report are:

1 The report calls attention to the importance of the technical institute in America in a more effective and convincing way than anything that has been previously expressed. This alone is a service of great significance and usefulness.

2 The report shows the very extraordinary success of the graduates of this type of schools. It demonstrates that for some reason, or in some way, the technical institutes included in this study have succeeded in getting results in their one- and two-year intensive courses that are comparable, in a very important particular at least, with those of the usual four-year courses of the regular engineering college.

3 The report furnishes a valuable picture of the stations in industry that these men enter, and it portrays the range and the variety of such positions as they are being opened up by the modern developments in organization and production processes that industry is using.

4 Perhaps the most striking fact of all brought out in this report demonstrates the extent of the need in industry for increased numbers of men who have had the special kind of intensive training that these technical institutes furnish. The findings are that industry is in need of 50 times the present supply of such graduates.

The author is to be congratulated particularly on the thorough way upon which he has collected his data, and upon the convincing manner in which he has assembled them to bring out the facts. At the same time, while expressing most hearty appreciation of all that has been accomplished, one cannot help a word of regret that the time and money at the author's disposal did not permit this study to include many lines of inquiry beyond those listed in the report. It would have been interesting, for example, if the study could have gone more into detail on the human side; if it could have estimated the numbers of boys and young men who today enter industry without special training, but who have latent capacities which enable them to profit by the kinds of training which technical institutes might offer. It would have been interesting if this study might have gone farther in the direction of analyzing the fields from which technical institutes draw their students and the methods by which they make the selection of those who are permitted to enter. It would also have been interesting if the intensive methods of training might have been studied more in detail so as to offer more complete explanation of many of the facts presented. It would also have been interesting, too, and of the greatest possible value, if the study might have gone far enough to suggest, in different industrial centers, the lines of new development which the technical institutes might most profitably undertake. These are only a few suggestions taken at random of the many directions in which further study in research would be of value.

President Hoover, in his inaugural address, laid emphasis upon the importance of discovering more and more ways to find leaders in every walk of life in order that one may keep pace with the new demands that science and invention are placing upon life. "One civilization after another," he stated, "has been wrecked upon the attempt to secure sufficient leadership from a single group or class." He stressed the need of drawing increasingly from the general mass and of giving full opportunity to rise, to the youth of America, through the select processes of education as far as natural capacity permits.

The technical institute is perhaps the most flexible type of educational institution at present. It lends itself naturally in large degree to carrying forward this ideal that the President has so well stated. But to accomplish this requires pioneer work far byeond anything that the author was able to find in the technical institutes described in the report. To find the answer there must be research of the first order; new ways to develop latent leadership for American industry and new pathways for "Young America" to achieve. What a magnificent challenge to the engineering profession in general, and to The American Society of Mechanical Engineers in particular!

[5] American Council on Education, Washington, D. C. Mem. A.S.M.E.

Author's Closure

The paper is in itself an abstract of greatly condensed character and presents only selected materials designed to supplement earlier partial reports. Mr. Williston's observations as to its limitations and his suggestions for further research in the distinctly human areas of the problem are wholly appropriate.

Three possible approaches to its problem were opened to the staff of the investigation. These might be called respectively the economic, the personal, and the social. The first is concerned with what industry needs in order to function efficiently; the second with what the individual needs in order to develop and use his latent powers to best advantage; and the third with the institutions which society needs in order to mediate effectively between the one and the other. With limited time, money, and human resources at his disposal an investigator must be pragmatic. He finds industry organized in large units and associations, disposed to cooperate. Existing institutions can also be enlisted as cooperating agencies, some willingly and some grudgingly, and their experience can be analyzed. But individuals are scattered, infinitely variable, and practically innumerable, making it a boundless task to survey them. The study is therefore primarily a study of industrial requirements, secondarily a study of existing institutions and their services, and only incidentally a study of individuals and their personal needs. This third aspect was not at any time out of the minds of the staff.

It may be recalled that the two full-time members had both had extended experience and wide contacts as personnel officers in industry, and the third had been for a time director of a school of industries. What Mr. Williston proposes is magnificent, but it is a task for years rather than months.

The slow and precarious growth of the technical institutes as a group has undoubtedly been due in part to the lack of solidarity among the existing institutions and their faculties. Wisely, these schools have sought to preserve a high degree of individuality and local adaptiveness and not to fall into ways of standardization. In doing so they have stood apart, emphasizing their dissimilarities and failing to make common cause. They were unable to create and enhance a recognized status of their own, being too often content to be known as non-this or non-that. Their teachers suffered from a sense of professional isolation. Their graduates had no nationally recognized credentials. No organization existed for common initiative. No appeal was made to the public imagination.

It would be unfair to close this discussion without acknowledging the invaluable service which the A.S.M.E. has done to the cause of the technical institutes through its Committee on Education and Training for the Industries, in creating a common forum for the discussion of these problems. Without the stimulus given by this committee, it is doubtful if the present study would have been undertaken.

MAN-52-8

Management of the Small Manufacturing Plant: Its Characteristics and Advantages

By CROSBY FIELD,[1] BROOKLYN, N. Y.

Having ascertained by the four standards of comparison of size of plant that small plants greatly predominate this paper suggests two reasons for this large proportion: first, that constantly changing needs are being fulfilled by new products, requiring plants in the pioneer and expansion phases of industrial life, which plants must be relatively small; and, second, the higher efficiency that small plants seem to possess.

In order to arrive at a basis of measurement by which plants may be compared, their differences in each of their activities are evaluated in an approximate fashion, and these form a composite figure which has great influence on the plant's chances of success. Although this factor has been quite generally understood, no name has yet been given to it; hence the name "degree of uniquity" is suggested, and the effect of volume and other operating influences on this factor are discussed.

In discussing the personnel of a small plant relative versatility is stressed and also the tremendous advantage enjoyed by the small plant in having the higher incentive of part ownership for the higher executives and the immediate and concrete interrelation between effort and resulting bonuses among the subordinate keymen. General organization, research, retaining of consultants, etc., are mentioned.

BEFORE proceeding to a discussion of the management of the small manufacturing plant three questions must be answered: First, what is a small plant? Second, is there a sufficient number of small plants to warrant consideration? Third, are their chances of continuing to operate sufficiently great to warrant an investigation into their characteristics of management?

What Is a Small Plant?

Naturally any question of size is purely relative, and there are many standards of comparison possible. The most frequently used are:

(A) Average number of wage earners employed
(B) The power consumed
(C) The value of production (sometimes modified so as to use instead the value added by manufacture)
(D) The capital invested.

When considered by any one of these standards, it will be found that plants group themselves by each standard in a similar fashion. These all show a larger number of establishments in certain groups than in others, although the relationships existing between groupings of plants according to the various standards may not be the same.

Again, these standards have to be considered from the viewpoint of comparison of the size of the plant, considering all manufacturing plants in the country as a whole or only those in the industry under consideration.

If any one industry be considered at various times over its life, its growth can be considered in four phases having quite distinct characteristics. These four phases are:

1 *Pioneer.* In this phase all of the four characteristics increase, and usually each shows very closely the same percentage of increase. This is the phase of the very small plant.

2 *Expansion.* During this phase (A) and (B) continue to increase, but (C) and (D) increase very much faster. This is the phase in which large and small plants are both found, and the total number of plants is relatively numerous to that to be found in the other phases.

3 *Consolidation and Stabilization.* In this period (A) may even show a decrease or, at any rate, a very slow increase; (B) usually increases quite rapidly; (C) increases slowly; and (D) tends to increase slowly or remain stationary. In this phase the number of plants decreases, but the average size increases.

4 *Disintegration.* During this period the industry is losing place to other newly arriving industries. The tendency is for all of the foregoing to show a decrease; (A) and (B) rapidly, (C) less rapidly, and (D) very slowly, sometimes remaining constant. In this period the average size of plant decreases. In rare cases the number of plants may actually increase, showing a transplanting to new locations and subsequent building up there, after the fashion of a new pioneer phase.

Obviously the main objective of management in each of the four phases may be quite different, but, as is shown farther on, certain characteristics, predicated upon size, predominate.

In this paper the index used is that of average number of wage earners, for two principal reasons:

1 The majority of the problems of management revolve about the question of labor, and it therefore predominately influences the characteristics of plant management.

2 The number of laborers is a common denominator not involving variation in price of product or in daily wage rates; it is therefore more general than the others when plants in various parts of the country or during different years are compared.

When it comes to defining a small plant in terms of number of wage earners, then authorities[2] certainly vary.

Cohn (1) mentions a small plant of 200 to 2000 men.

Dennison (2) gives the following interesting classification:

Small plants up to 500 employees

---

[1] Vice-President, Brillo Manufacturing Company; President, Flakice Corp. Mem. A.S.M.E. Mr. Field holds the degrees of B.S. from New York University, M.E. from Cornell University, and M.S. from Union University. From 1912 to 1914 he was associated with the General Electric Co., and during the following year was engaged in private consulting practice in New York City. From 1915 to 1917 he held the position of chief engineer of the Standard Aniline Products, Inc., resigning to enter the Ordnance Department of the U. S. Army. Upon his return to civil life he became engineering manager of the National Aniline & Chemical Co., Inc.

Contributed by the Management Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Number in parentheses that follow the names refer to the bibliography at the end of the paper.

Plants having 500 to 1000 employees
Medium plants, 1000 to 5000 employees
Large plants, 5000 to 10,000 employees
Very large plants, 10,000 or over.

On the other hand, other authorities consider the number to be as follows:

Cordeal (3), 100 to 300 men
Alden (4), under 125
Cockshott (5), 100 to 150
Dykestra (6), under 150
Machinery, London (7), 50 to 150
Bailey (8), 150 to 400
National Industrial Conference Board (19), 250.

TABLE 1 DISTRIBUTION OF ESTABLISHMENTS EMPLOYING SIX OR MORE WAGE EARNERS, BY NUMBER OF WAGE EARNERS PER ESTABLISHMENT, 1914 TO 1923[a]

	Number of establishments			
Wage earners	1914	1919	1921	1923
6 to 20	53,954	54,317	53,771	54,609
21 to 50	22,879	25,176	23,898	25,212
51 to 100	11,070	12,370	11,047	12,346
101 to 250	8,465	10,054	8,532	10,023
251 to 500	3,108	3,596	2,916	3,835
501 to 1000	1,348	1,749	1,241	1,784
Over 1000	648	1,021	645	963

[a] It is assumed that, by omitting all establishments with less than six wage earners, the fact that the censuses of 1914 and 1919 included establishments whose products were valued at less than $5000, whereas the later censuses did not, may be disregarded.

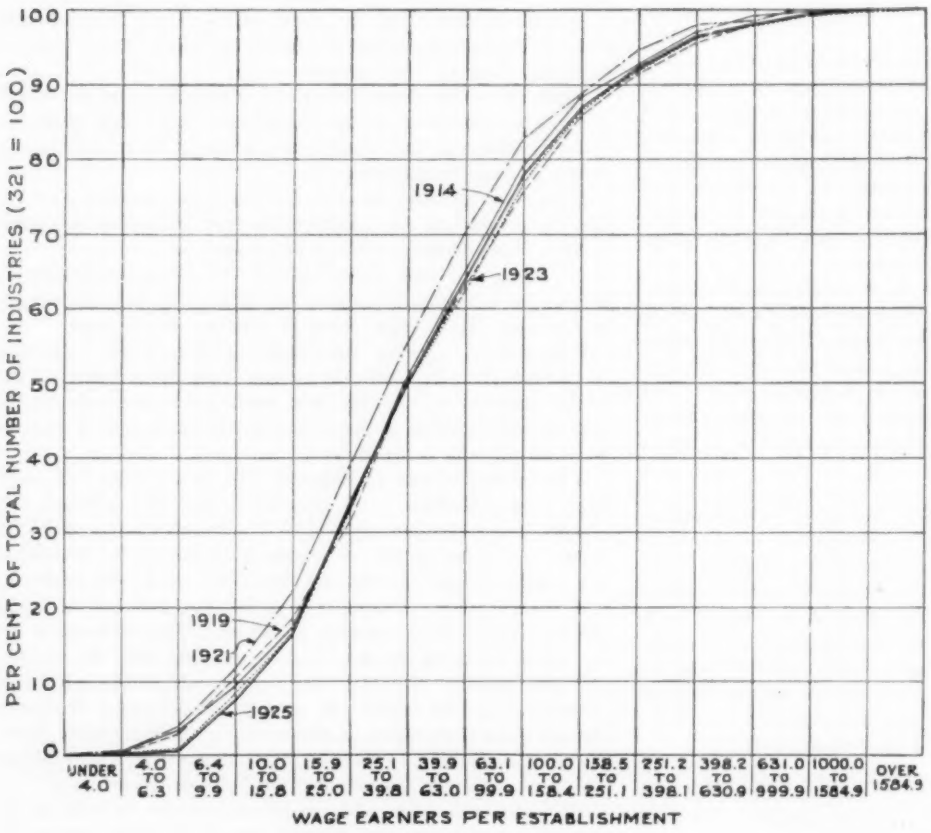

FIG. 1

In spite of these widely divergent views, Thorp, who has studied this question probably more than any one other man, in his Census Monograph (9) gives a dividing line of 250 employees, whereas in a later study (10) he gives a chart (Fig. 1) showing the frequency of plants. This illustrates the tendency for the plants to concentrate at two peaks: first, a peak at about 100 employees per plant, and next, a peak at about 20 workers, there being an actual decrease in the number of large plants. He further discusses in considerable detail a study of 321 industries making up this chart, which employed from an average of 1.2 in the cheese industry to 1086.9 in the rubber boot and shoe industry. There were seven establishments having over 500 workers each and 70 with over 100.

Thorp (11) also gives a tabulation of this. (See Table 1.)

Note that the number of plants in the United States employing over 1000 men is less than 1000. If there be added to the able those 90,000 small establishments employing less than six wage earners, the number of plants to be classified as small is surprisingly large; in fact, no matter what divisions the authorities quoted may select for their distinction between small and large, all are agreed that the small establishment shows no tendency to disappear.

We are unable to determine whether the small plant exists in such large proportion because of the fact that our numerous and always increasing number of wants are creating new industries, which being in the pioneer or expansion phases naturally are in the early stages of their growth, and therefore relatively small, or whether it is not a question of the small plant having a certain inherent superiority which permits it to compete. As Thorp so succinctly puts it in referring to two industries he has just finished studying, (12) "both of which confirm the well-established principle that at any given time and at any given stage of the industrial arts there appears to be a size of plant that is most efficient." We may perhaps amplify the statement by pointing out the influence of the stage of transportation and communication, and also the influence of density of population and marketing machinery. Thorp gives a summary of advantages possessed, respectively, by the large and the small plant (13), in which he mentions certain economies in production, in marketing, in management, and in financial administration. He also classes certain industries which are more eligible for large enterprises than others. He says:

> In general, the following types of industry appear to have developed production on a large scale to the greatest degree:
> 1 Industries which require a large capital investment, particularly in plant and equipment: Sugar refining, copper smelting, steel mills.
> 2 Industries which are monopolies, and which have a sufficiently large market to make operation on a large scale feasible. This includes artificial monopolies, such as those based on patent rights, as well as the monopolies by nature: Public utilities, manufactured ice.
> 3 Industries in which a natural resource is required and in which that natural resource is limited in amount and localized in geographical distribution: The manufacture of lead and zinc products.
> 4 Industries in which the product is capable of standardization and particularly in which a test for quality is required: Sugar, salt, meat packing, etc.

5 Industries in which the product is highly complex and can be constructed, therefore, only by an intricate fabricating system or a large and diversified organization: Typewriters, adding machines, textile machinery, and automobiles.
6 Industries in which the product is large in size, requiring complex equipment for construction and large capital investments: Shipbuilding, locomotives, ordnance.

Some of the general types of industry in which small-scale manufacturing is necessary are:

1 Industries whose product cannot be standardized and establishments which attempt to make products to suit the differing tastes of consumers. Such industries produce "tailored" suits, high-grade furniture, art goods, finely bound books, etc.
2 Industries producing for a small market, such as those manufacturing artists' materials, nets and seines, models, and patterns.
3 Industries in which the local market is small and whose product has a high transportation cost. In the manufacture of artificial-stone products, or bricks in many localities, the activity could never be conducted on a large scale because of the limitation of the market for its product and the expense of transportation.
4 Industries in which the material used is widely scattered and cannot be concentrated because of high transportation cost or rapid deterioration. Cheese factories and cider mills may be included in this class.
5 Industries in which skilled labor is the chief element, such as engraving, job printing, etc., whose products are really services rather than commodities.

The foregoing classification is believed to hold when a cross-section is made of all industry at any specific time, but is believed to leave out of consideration several factors primarily connected with growth.

It is obvious that a new industry can start only in a small way. This new industry may be merely specialization in one of the branches of a large industry and the development of that branch until it becomes a specialty by itself. The fundamentals remain the same, however, as the pioneering can be done only on a relatively small scale to be successful.

The foregoing data indicate that a plant is small when it has an upper limit of employees of from 100 to 250 workers, that this type of plant forms the greatest in percentage of total establishments (though producing barely more than half the total output), and that there is no tendency for it to disappear; on the contrary, it would seem as though it was even better than holding its own. As the questions asked in the first paragraph have been answered, the author will now proceed to the discussion of the details of management of the small plant.

Protective Influences

What are the criteria of success in management? Many have been proposed, but the two that apparently have the most widespread acceptance are a continuing increase in gross volume accompanied by a continuing increase in net profit. The ratio of the latter divided by the former need not necessarily increase, nor even remain constant, to show success; but too great a decrease indicates a change in conditions to be pending that acts as a forerunner of possible difficulties.

These criteria come as judgment after the act; what can be used before the act as a prediction of result?

It is well recognized, as Kimball states (16), that "every manufacturer must expect to rest his chances of success on one of three general factors; namely, monopoly, quality, or price." (Some authorities consider as a separate factor what they call service, the ability to deliver the material when or where wanted, or in the special shape desired.) As is usual with general factors, they must be studied carefully in their specific aspects as applied to the individual case before rating their influence. Thus monopoly, whole or partial, may be due to patents, to strategic location, to favorable sales combination, to indirect control of the purchaser by influences other than those due to the business in hand, to reciprocity, to local pride in a local industry, to transportation peculiarities, to franchise or other legislative control, and countless other factors.

Looking at these general factors from another viewpoint, and their numerous interrelations, it is quite likely that they in turn are but aspects of a still more general factor. This more general factor further predetermines the proper size of plant, of selling organization, of financial structure. The author ventures to give this factor a name, with full realization of the fate that usually falls to those who risk too broad a generalization, especially when accompanied by attempted definition of new terms, because it is believed the advantages of having such a term to apply to the daily solution of management problems warrants the effort.

Manufacturing plants and their selling organizations exist for the purpose of supplying commodities to fulfil human needs. With each human being the specific definition of that need varies slightly from that of his neighbor, but it is possible to group individuals into classes whose needs can be fulfilled within a range for the fulfilment of which it is possible to design a plant and organization. The only excuse for such a plant is that it has selected a field for operations in which it has advantages which render it unique. Unique is defined (17) as "being without a like or equal; single in kind or excellence; sole." The noun uniqueness has a general overall flavor; hence the term "degree of uniquity" is suggested as implying a relative degree of compliance with its original or logical uniqueness. A firm may be unique in the articles it produces, the process of manufacture, the way it sells, the territory in which it sells, the trade to which it sells, its fashion of shipping, the method of receiving its pay, its advertising, or even the power given it in the public mind by the personality of one of its members or employees. The degree of uniquity it enjoys is demonstrated by its degree of monopoly, or the quality or price of its products, and is accompanied by its growth in volume and profits.

It naturally follows that a plant should be as large as it can without sacrificing too many degrees of uniquity, for there is no room for two plants having the same degree of uniquity. One or the other must gradually withdraw from parts of territory or types of customer, thus changing the relative degree of uniquity.

As the plant grows, there is constant temptation to take on new lines, to expand territory, or to cut prices. Each such step is accompanied by a decrease in the degree of uniquity, with its subsequent dangers. Growth by expansion of territory is usually the least dangerous, because of the universality of similar needs among our countrymen everywhere, but every small enterprise pays dearly for its right to claim "national distribution."

The realization of the need for a large degree of uniquity in a small plant to protect it from competition is one reason so many small plants start as manufacturers of a specialty. If fortunate enough to select a specialty that is going to grow into a huge basic industry, such as steel, automobiles, etc., the growth of the plant will be great. It is, however, not unusual for a specialty of a small industry to grow to a size larger than the original industry and to completely overwhelm it, changing not only its entire aspect but the ownership of the controlling companies.

This is often accomplished by acquiring a considerable degree of uniquity in only one phase of operations, such as the discovery of a new use by a slight modification of manufacture or marketing, or by a change in manufacture due to an invention.

Every plant, large or small, should devote its attention to maintaining or even increasing its composite degree of uniquity, and in certain phases the advantage therein lies entirely with the small plant. The large company must have volume; to get volume it must sell everybody, it must sell everything (i.e., a complete line), it must sell everywhere. Each approach to universality in each phase lowers the degree of uniquity, save perhaps in actual production where the greater amount of available money may render possible the purchase of a greater degree

of uniquity due to research on product and process. It is a strange commentary that the large companies availing themselves of this method of obtaining uniquity is relatively small.

There are certain advantages which must ever remain with the large plant. Foremost is in obtaining favors that money can buy. This gives the larger plant a tremendous superiority in bargaining power, not only in the buying of its raw materials at the lowest possible prices, but also in competitive selling, which after all is a kind of buying where the flow of money is reversed. Not only in selling its products, but in selling its securities and in patent litigation, the money power of the large plant makes a formidable obstacle to the small plant against which there is only one weapon for the small plant to use—initiative almost mounting to daring, (14) in strengthening its position in so far as degrees of uniquity are concerned.

From the viewpoint of the small plant, in sizing up its opponent, the large plant, it must consider it very much from the viewpoint of the inferior army in combat. The victory does not go to the general with the largest forces nor the largest supply, but to the one who can get, to paraphrase General Forrest, "the mostest men [and the mostest supplies] thar fustest."

The small plant that endeavors to compete with its larger neighbor by making everything that the larger plant makes, puts itself in a very unfortunate position. The strength of the small plant as detailed is essentially specialization, either specializing in product or in method of manufacture, or in marketing. This specialization in marketing may comprise intensive work in a limited territory or a new and novel means in a larger territory. The specialization in the method of manufacture usually comprises the development of special machinery, preferably protected by patents, affording the small plant an opportunity to realize on its manufacturing cost difference. All these advantages merely increase its uniqueness when compared with its larger competitors.

A plant normally starts, therefore, because it is in a unique position to fulfil certain needs. This composite degree of uniquity is composed of numerous factors, each representing a degree of uniquity of one activity of this plant compared to the same activity of other plants. The precise numerical figure for the measurement of this degree of uniquity would be difficult to arrive at, but may be normally considered to be the unit dollars-and-cents advantage over other ways of fulfilling that need. As the plant grows it soon arrives at a place where due to expanding business one of the component factors of the composite degree of uniquity becomes greatly diminished. It then becomes a matter of much concern whether to still further increase the volume and thus noticeably diminish the overall degree of uniquity or whether to maintain that degree and permit the volume to remain constant. The ultimate size of plant, therefore, should be that size which can produce the greatest volume with the least marring of its degree of uniquity.

Generally speaking, there is room for only one plant having a certain degree of uniquity; consequently, the plant should aim to become the "largest of its kind" within the shortest possible time after starting. This, of course, is just another way of saying that the plant should be the largest having that degree of uniquity.

One movement that has gained considerable momentum in the past decade has been the so-called "integration of industrial operation." (20) This is an attempt to obtain the advantages of volume and of uniqueness in the same organization, maintaining the plants of a size and number tending to the greatest degree of uniquity and simultaneously providing an overall volume that warrants those advantages that accrue alone to size. The integration may not only be along the matter of plants, but also sales organization or other aspect of the business. In each case the aim will be found to be the same, and the greatest advantage accruing to the integrated industry is its bargaining power and those other advantages that money alone can buy.

Characteristics of Personnel

Specialization as a method of strengthening the small plant's uniqueness has been emphasized, but when the personnel is examined, a strange paradox presents itself. For success, the small plant requires the greatest specialization in product and method, and yet the greatest versatility in the mental attributes of the men concerned with management. A few moments' reflection will show this. A man's time may be occupied either by performing one function and applying it to a number of things (the so-called functional organization) or by performing several functions connected with some one thing. When the plant is small enough the man at the head must naturally perform all three functions in the tripod of manufacturing—to wit, production, sales, finance. As the plant grows larger, specialization, or rather functionalization, takes place, and the president hires a factory manager, a sales manager, and other functional heads, but he himself in the small plant must perform all these functions.

One of the characteristics, therefore, of the personnel of a small plant is its versatility. Each man in the plant, from president to foreman, will be found to perform a larger number of functions than a man of corresponding position in a large plant. Indirectly this versatility of mind points the reason for so many failures in small-plant management. Because a man is versatile he is inclined to get into several businesses or try to make his business go into related lines. He does this not only because of his desired increase of income, but also because of this versatility of mind.

Strange to say, this versatility of mind is not so common in an industry just beginning, and perhaps that is one of the reasons so many small plants are never able to survive the pioneer phase. The hardships of pioneering require a degree of perseverance that cannot even politely be termed anything but obstinacy. Obstinacy may not necessarily imply a low order of intelligence, but the results of its application in practice usually preclude the acquisition of that culture which makes for versatility. Culture and intelligence are not necessarily one, but are more often found together than either one by itself. Certainly the lack of income in an industry not yet past the pioneer stage does not attract men having that culture and who are usually comfortable in a better established line. That "intelligent patience" (18) which is the prerequisite for all research and other pioneer work fades rapidly when confronted with an empty stomach.

This required versatility is well brought out by Cole (21), who compares the simplicity of ship navigation in two dimensions, or even that of the air in three dimensions, with that of a manufacturing plant with its manifold problems—it is N-dimensioned. In any one of its numerous dimensions may lie the hidden rock of failure.

Alford and Hannum (15) in their startling Table V show that the small plant has the advantage in the output per man. Just why this should exist is of course a matter subject to many opinions, but the author firmly believes that one of the principal reasons is the fact that those responsible for the details of operations affecting costs are closest to the profit and loss in the industry. In other words, there is no incentive like ownership in an enterprise, and when the manager is part owner and when the superintendent and foreman share in the form of bonuses from the profit attained by their operation, then each has the greatest incentive for efficient management. It is not that there is any particular difference in the desire or willingness on the part of the men, but the cause and effect are so closely related

and the one follows the other so promptly that there can be no mistaking their relationship. In a small plant no mystery exists in the minds of the men making and selling the product of the relation between costs and profits. There are no central office charges or huge overheads to be absorbed, and in their absorbing to distort charges. Each foreman can figure concretely how many of a kind he must make with a new machine in order to pay for it or not to affect either the profits of the company or his own bonus.

In the management of the small plant the keeping of the overhead to a minimum is a prime requisite. There is nothing that chews up profits quicker than useless records, and records all have that well-known tendency to become useless unless they are constantly used. In order to be constantly used, they must be of prime interest to those most concerned. In one plant the policy has been to keep no basic records unless somebody's pay depends on it. All the production records are under the paymaster, and it is indeed rare that errors enter, for any error is going to affect somebody's pay, and naturally if this is affected in the wrong direction an immediate howl is made by the party affected. If, on the other hand, they are affected in the other direction, then the foreman and his bonus create the other situation. A summary of these records is studied by the operating committee twice a week at a meeting which is primarily for the study of these records, which have of course been boiled down by the paymaster into summary sheets. At this meeting any other business that may be pressing is brought before this committee, but pains are taken to let the committee understand that in working as a committee it is purely advisory, the responsibility for functioning remaining with the individual.

Type of Organization

This mention of the "operating committee" brings up the question of the type of organization for the small plant. Any manufacturing organization naturally divides itself along the lines of its three principal functions—sales, production, and finance. In the smallest-size plant all functions are headed up by one man, who frequently takes on as silent partner a financial backer. In the larger size of small plant the production or sales is alone handled by this one man, the other functions being handled by another, who also acquires a substantial share in the enterprise. From this split-down in each of the two operating departments, sales and production, the organization is decidedly line, the versatility of the keymen being depended upon for staff functions. In the next larger-size plant, certain staff functions may be split off, generally a superintendent to handle labor, a plant engineer to handle equipment design, construction and sometimes maintenance, and the office, including paymaster, and sometimes purchasing agent. Similarly, the sales organization is separated from credits, and territorial divisions enter.

Depending upon the nature of the business another function becomes sometimes most important, particularly in those industries which are of a contracting or jobbing nature. That is the function of designing for proposals or estimating. Whether or not the estimator be part of the sales organization or part of the factory organization depends greatly upon circumstances, but normally will be found to be under the engineer who in a small plant is both plant engineer and design engineer.

Our typical small plant now has 100 to 250 employees, and if it continues to grow it must be classed as a large plant. Our key personnel must still remain versatile, and comprises only seven men, enough still to share directly in the profits by having a share in the ownership. These men are the chief executive, sales manager, credit manager, production or factory manager, superintendent, engineer, and purchasing agent. Further profit sharing among territorial sales managers and foremen is easily obtainable by means of commissions and bonuses, the close contact of the heads with affairs and men rendering such procedure profitable. This gives the greatest incentive to effort, and, as has been stated, is probably one of the reasons for the greater efficiency of the small plant.

For committees, which should be purely advisory, only two in the factory, safety and operating, and one comprising sales and credit are desirable. At these conferences hidden difficulties are frequently brought out and settled.

Research and Development

Since the small plant must keep down overhead, it suffers from lack of staff, and it therefore would seem that the small plant is the ideal client for the professional consultant. Obviously the small plant cannot compete with the staffs and laboratories of the large concern, having a staff of a caliber and size to take care of all their needs; nevertheless, the retaining of professional consulting services and realizing upon them forms one of the most difficult problems of the small-plant manager. The small plant must specialize, and by conquering its specialty it very soon gets out of the depth of the professional consultant who may then become even something of a liability. On the other hand, the small plant cannot be expected to keep in touch with the advance of the art as a whole; hence a compromise must be effected whereby the small-plant manager is brought down to date by the consulting expert on all matters connected with the art as a whole, retaining for his own small staff the specialization work that pertains to his own manufacture.

This requires, of course, versatility on the part of the plant manager, and it may further be displayed not only in the hiring of engineering and manufacturing consulting services, but further in the retention of other types of professional consultants, such as patent attorneys, auditors, and the like. The man at the head of the small plant must be versatile enough to make proper judgments when presented with the technical facts and advice of the various consultants he should retain.

One place that the small plant very frequently falls down is in the development of its own machinery and equipment. It is too easy to buy standard equipment and operate it. In so doing the plant is not putting itself in any way in a position to compete with its rival, who is of course going to receive the benefits of the same machine. There is no resulting favorable differential in uniqueness obtained. The modification of a standard machine to produce a specialized product is one of the surest ways that the small plant can achieve success.

Ranck (22) in an able article tells how his concern obtained great advantages in a specialized product by developing machines twice as large and able to handle material twice as wide as could be provided them by the standard machinery manufacturers. This resulted in a small plant having the largest machines and enabled it to undertake work that the large plants with their small machines could not do. Mr. Ranck, as might be expected from such a course, evolved the following three suggestions for a small plant:

1 Make the best product
2 Watch costs; fight them with daring
3 Watch shifting markets, particularly with respect to the salability of the product.

Distribution Effects

Depending as it does upon volume, the large plant naturally tends to manufacture more of its own raw materials, which means more products to use or sell, which means an ever-increasing line of products, marketed more and more upon a price basis and with constantly increasing fixed capital investment.

All this tends toward a rigidity of operation, a building up of inflexible policies and other attributes that render it comparatively immobile, while the small plant can succeed better because it can move quicker. In order to maintain its mobility it must be in close contact with its customers.

Generally speaking, the more successful small concerns are found closest to the ultimate consumer, working back into production of its raw materials only as they increase in size, and the larger concerns are found nearest the crudest materials, such as mines or other original sources of raw material. This is good policy in that it permits the more ready establishment by the small plant of that uniqueness referred to. The contrary policy, of manufacturing for a large plant, thus becoming a so-called "satellite plant," is frequently profitable, but exceedingly hazardous.

Distribution costs form an increasingly important share of the total. In selecting the right customers and the proper market the small concern has several advantages; the large concern seeking to dominate the line must sell everybody, and in selling everybody takes many accounts at a loss, whereas the small concern with limited output can be more selective in its accounts.

Cole (23) refers to the most usual "entangling alliances" to be avoided as dependence upon a single or uncertain source of supply of raw materials, a single product, or a single customer or outlet. Yet if the composite degree of uniquity be great enough, a single product is often the very best guaranty of continued success. In order to accomplish this, however, it must be protected by a trademark and a distribution that make it difficult for a competing brand to get into the ultimate consumers' good graces.

Summary

There are four standards by which plants are compared according to size, which are: wage earners, power consumed, production value, capital invested. By any such standards of comparison the small-size plant is found to be predominantly in the majority of the number of establishments, and detailed investigation along the lines of that of comparison by means of wage earners has been given. There are four phases of the life of industry, called pioneer, expansion, consolidation, and disintegration, and the general characteristics of relative number and size of plants in each of the four phases have been discussed. It is probable that the preponderance of small plants is due to two factors; first, the large number of industries in this country which are at present in the pioneer or expansion phase, during which two phases the size is relatively small; the second factor is demonstrated to be a certain type of superiority in efficiency that plants of a certain size have been found to attain. Whether this certain size can be called small or large depends upon a variety of factors, but it is certain that the most efficient plant is neither the very smallest nor the very largest of its kind. The conditions under which the small plant or the large plant may attain this most efficient size have been discussed, and it is believed that the small plant—i.e., the plant having less than 250 employees—will be found in most cases to be the most efficient.

In studying the relative advantages of the small and the large plants, in addition to the usual factors of monopoly, quality, and price given, it is believed that a more general factor termed the degree of uniquity which takes into consideration these three and in addition numerous other factors, all external to the organization and size of the plant itself, and which may be either favorable or unfavorable, should be introduced and used. The most efficient size of plant would seem to be that size determined by a compromise between the degree of uniquity and the volume of production. This balance may be slightly changed from one side to the other by matters of personal efficiency of the guiding minds of the organization. Several of the factors affecting this relationship have been discussed.

Among the characteristics of personnel discussed, that of relative versatility between positions in the small and large plants has been mentioned, and the greater versatility required by all the personnel of a small plant is seen to be both limited in supply and at the same time to be responsible for much of its efficiency.

One of the strongest advantages enjoyed by the small plant is believed to be the close relationship between incentive and effort produced by the element of share in ownership that is much more likely in a small than a large plant. In addition, is the fact that cost and profit, one person's effort and its result, are immediately seen instead of the long-time lag that comes in large organizations, not to mention the chances of losing that relationship in the whole averaging of a large number of factors, sure to occur in the large plant.

Some remarks regarding the organization of the small plant have indicated a line organization with very few staff positions. Committees, when used, should be purely advisory; the carrying out of the suggestions remain the responsibility of the executives in the line and according to their line responsibility. Some remarks on internal research and development and the retaining of consultants indicate the difficulties of the small plant. Inasmuch, however, as this is one of the surest ways of maintaining its degree of uniquity, it must be one of the most carefully studied. Remarks on the effects of distribution and methods of combating have indicated that not only must the small plant be studied internally, but also from the aspect of its distribution and keeping in mind that increasing distribution is one of the principal factors tending to reduce the degree of uniquity.

Bibliography

(1) Cohn, R. F., "The Small Plant Discovers Applied Science," 1930, *Factory & Indust. Manag.*, v. 79, pp. 52–4. Tells how applied science rather than pure research may be carried on in the small factory. Savings realized by a small metallurgical plant illustrate the value of research and good management in a small plant of 200 to 2000 men.

(2) "Recent Economic Changes," McGraw-Hill Book Company, 1929, p. 500.

(3) Cordeal, E., "Management Problems of the Small Factory," 1921, *Indust. Manag.*, v. 61, pp. 306–10, 370–3; v. 62, pp. 114–19, 182–7. Shows how a plant employing from 100 to 300 men can apply management methods and planning systems to its advantage. Points out some of the common difficulties met in trying to determine costs in the small factory; he is concerned with a cost policy, not cost figures. Supervision and inspection are given special consideration.

(4) Alden, M., "Big-Shop Methods Pay in a Small Shop," 1925, *Factory*, v. 34, pp. 750–2, 780, 782, 784. The author gives his experience in the application of big-shop methods to a plant of 125 employees.

(5) Cockshott, M. C., "Maintenance Problems in the Small Plant," 1925, *Indust. Engr.*, v. 83, pp. 567–72. Discusses the difficulties met in plants employing 100 to 150 men, as regards skilled labor, specialized repairs, getting the best service from belt drives, lubrication of mill bearings, use of pressure steam.

(6) Dykstra, J. E., "Factory Methods for the Small Manufacturing Plant," 1925, *Am. Mach.*, v. 63, pp. 569–72. Despite the common assumption that management methods are not adapted to the small plant, the author shows how this system is working successfully in a plant employing about 150 men. A flexible system is assured, and production and costs are easily controlled.

(7) "System in Small Engineering Works," 1926, *Machinery* (London), v. 29, pp. 139–41. A general outline or a system of management which has been successfully employed by an engineering factory employing 50 to 150 men.

(8) Bailey, S. H., "Systematic Control of the Small Works," 1929, *Cassier's Indust. Manag.*, v. 16, pp. 275–8. Gives an organization chart for a factory employing 150 to 400 employees. Suggests a layout for a small plant, and an operating plan which, it is said, will work without a staff of efficiency engineers and will at the same time show profits.

Manag.*, v. 69, pp. 208–12, ref. 23, pp. 291–5, ref. 21, pp. 360–4; v. 70, pp. 40–5, 265–9; v. 71, pp. 27–31, 106–11, 235–40, 311–16; v. 72, pp. 54–9, 283–7 Answers, among other important questions, "Can the small shop survive, and how?" Takes up such subjects as the importance of a fixed policy, material in the small shop, the importance of the product, supercompetition and the small plant. Is the "complete line" advantageous? Goodwill as a permanent asset, cooperative buying and selling, some aspects of the competition for labor.
(22) Ranck, Z. W., "I'd Rather Run a Small Business," 1929, *Factory & Indust. Manag.*, v. 78, p. 1063–5. The author is the President of the Crystal Tissue Co., Middletown, Ohio, a small plant specializing in tissue papers. He recommends that the small manufacturers make the best product in his field, that he fight costs, that he stabilize the market. Gives the advantage of the small plant from a business and personal standpoint.

(25) Leach, E. W., "Organization and Management of the Small Shop," 1921, *Am. Mach.*, v. 55, pp. 81–84, 190–3, 262–6, 338–41, 438–41, 513–16, 592–5, 671–3, 754–6, 883–5. Discusses the necessity of organization in the small plant, tells how to analyze manufacturing problems, market analysis and different ways of reaching the ultimate consumer, financing the company as a corporation or a partnership, a management system including simple cost keeping, how to figure profits, efficient service in filling the customer's order and how to get it, small shop bookkeeping, going after the business, cooperation necessary between producers and management.
(26) Baker, H., "Considerations on Factory Size and Efficiency," 1922, *Engr.*, v. 133, pp. 292–4. Contradicts the view often taken that plant efficiency increases with size. The author attempts to prove that it all depends on the product produced, but that as a general rule the small factory is most efficient. To prove his point he calculates the efficiency of the one-man plant, and then shows the effects of division of labor up to the point of maximum efficiency, and finally gives a formula for calculating the ideal size of factory.
(27) Cole, D. S., "Minimum Shop Operation Without Loss," 1922, *Indust. Manag.*, v. 63, pp. 96–7. Describes the operation of a small industrial plant during a period of curtailed manufacturing operations, without allowing overhead to cause losses.
(28) Whitehead, A., "Establishing a Small Engineering Works," 1922, *Eng. & Indust. Manag.*, v. 7, pp. 502–6, 540–2, 571–3; v. 8, pp. 3–5, 39–41, 75–7, 121–3. Gives advice in the selection and appointment of a staff for a small factory; the organization plan, functions of each department, and the division of labor within the departments; what the managers might reasonably expect from the production department.
(29) Brown, G. C., "Profitable Methods for the Small Factory," 1924, *Manag. & Admin.*, v. 7, pp. 161–7, 305–10, 431–6, 567–72, 683–8. Discusses the special fields open to the small factory; the distinction between the large and the small factory; the inadequacy of management in small plants; outlines some profitable methods for a small organization in which standardization is guaranteed; wage incentives and profit-sharing; distribution of overhead to jobs.
(30) Ross, H. W., "Management Difficulties in Small Factories and Their Solution," 1924, *Indust. Manag.* (London), v. 11, pp. 207–8, 377–9, 467–8, 470. Gives some common examples of difficulties in the purchase of materials and in the acquisition of a credit rating.
(31) Carpenter, C. U., "Making a Success of the Small Manufacturing Business," 1925, *Manag. & Admin.*, v. 10, pp. 125–8, 195–8, 287–9. A general study of the application of management to a small business in its early stages; management in the shop, and in selling its product.

(33) Lynch, F. J., "Even-Flow Production; What It Can Mean to the Small Plant," 1925, *Factory*, v. 35, pp. 909–10, 950. The president of the Sun Tube Corporation, Hillside, N. J., tells a cheerful story of the opening and running of a small factory. The one described manufactures collapsible tubes for shaving cream, tooth paste, etc.
(34) Wherry, H. P., "Management Problems in the Small Plant," 1926, *Mfg. Indust.*, v. 12, pp. 207–10, 257–60, 355–8, 419–22. Shows the similarity in the problems of the large and small plant; the advantages of the large plant; the place of research in the small plant; the small company's handicap in advertising.
(35) Cole, D. S., "Solving the Problems of Composition in the Small Factory," 1927, *Indust. Manag.*, v. 73, pp. 80–90, 155–60, 229–34. Discusses the possibilities of stimulating business by an analysis of products; the possible elimination of waste by the application of research; grouping of small plants of allied industries; the small plant's handicap when it comes to quantity production.
(36) Dwyer, P., "What Is Wrong With the Small Foundry?" 1927, *Indust. Manag.*, v. 74, pp. 33–9. Points out that although the small foundry occupies a well-defined and necessary place in industry, it is in a highly competitive field, where exact and scientific methods are used and where guesswork has no place.
(37) Simonds, H. R., "Improving Small Plants Economically," 1927, *Iron Tr. Rev.*, v. 81, pp. 1–3. Tells about the reorganization of the Coates Clipper Manufacturing Company, Worcester, Mass., according to modern manufacturing principles, the gradual replacement of old equipment, and the development of an efficient and profitable small business.
(38) Wherry, H. P., "New Methods Increase Production 100%," 1927, *Mfg. Indust.*, v. 13, pp. 41–4. Describes some cost cutting which has meant substantial savings for one small plant.
(39) Wherry, H. P., "Results From Reorganized Financial and Sales Methods in a Small Plant," 1927, *Mfg. Indust.*, v. 13, pp. 115–19. Tells briefly how accounting and production control have simplified the work of the plant of Rossendale-Reddaway Belting & Hose Company.
(40) Alexander, A., "What of the Small Factory?" 1928, *Nation's Business*, v. 16, pp. 64, 67–8. Gives a short statistical summary showing that the small manufacturer has the same chance he has always had. "The race is keener today, there are more people in it, but the prizes are greater."
(41) Hoyt, C. W., "What Chance Has the Small Manufacturer?" 1928, *Nation's Business*, v. 16, p. 56. Direct competition is said to be possible, provided the small manufacturer selects one product, redesigns it, and subjects it to unique and intensive marketing.
(42) Pavey, W. B., and others, "Making a Profit in the Small Plant," 1928, *Mfg. Indust.*, v. 15, pp. 187–90. Points out that the principle of industrial management, when applied to the small plant, is just the same as when it is applied to the large; the difference is in the application. Gives several advantages possessed by the small plant, as seen by officers in such organizations; the chief disadvantage is said to be the multitude of duties placed on executives. Research is considered imperative for the small factory.
(43) Roberts, G. E., "Small Concerns Still Possess Advantages," 1928, *Comm. and Finance*, v. 17, p. 920.
(44) Swanson, A. E., "Advantages of Knowing Costs," 1928, *Mech. Wld.*, v. 84, pp. 81–2. Shows how a small plant may develop rapidly into a large one without having sufficient records of costs in its development stages. Recommends that every manager familiarize himself with the details of costs in all stages of business.
(45) Dykstra, J. E., "Management of Small Industrial Plants," 1929, *Cassier's Indust. Manag.*, v. 16, pp. 51–3. Discusses the determination of a plant's production capacity in order to practice control in accordance. Some system of time study is considered indispensable to the small factory manager; other important factors are grouping of equipment, use of new tools, and intelligent buying.
(46) Norton, C. F., "Why We Prefer to Stay Small," Howell Electric Motors Company, 1929, *Printer's Ink*, v. 147, pp. 133–4.
(47) Hopper, S. J., "Plant Growth Affects Management," 1930, *Iron Age*, v. 125, pp. 75–6. Outlines in a general way the problems brought about by the expansion of a small factory, especially in the selection of the minor assistants and in lowering the production cost of the product, in order to justify the factory expansion.
(48) Burnham, "Building Your Own Business," 1923. This non-technical treatise is one of the most concisely stated and brilliantly arranged polemics in favor of the small company. It gives forty-six cases illustrative of the various points made, and is a book that should be in the library of every engineer.
(49) Reference to dictionaries demonstrates that the term "uniquity," although at present classified as rare, not obsolete, is etymologically correct, whereas "uniqueness" is not. "Unique" is Latin and should take the Latin suffix "ity," not the Anglo-Saxon "ness;" thus, ubiquity.

Discussion

D. B. CHARTERS.[3] It is the writer's belief that some of the good points claimed for the small plants have been slightly exaggerated, and he would like to indicate some things which might point to other conclusions being the more correct.

(1) The versatility of those in charge of the plant may well be a strong factor in the success of the concern, but the control by one or two persons has this disadvantage in that their errors in judgment may have an immediate and disastrous effect upon the small plant. Could these executives be always correct in their judgment the quicker action secured by their close contact with their plant is of course highly desirable, but in the larger plant projects must pass through several persons, generally experienced; so that while there may be some delay as compared to the smaller plant, when the project is finally complete, it is much more likely to be workable in all respects. The writer has had some experience along these lines and recalls very clearly instances substantiating the statement.

(2) Many small plants attain their "uniquity" as to price by frankly copying the output of the larger concern. All elements of expense distribution, as regards design and development, are thus avoided by the small-plant manager, and while the price of his product may be lower and the product itself just as good, it seems hardly fair to credit this entirely to the acumen of the small-plant manager.

(3) Efficiency is a broad term, but if it were based in a general way upon length of life, service rendered to the public, the ability to pay reasonable dividends year after year, surviving good times and bad, steady employment, care of the old employee, then the large plant surely is just as "efficient" as the small plant.

(4) It seems that the author has stated the case perfectly for the really successful small plant when he says, "A single product is often the best guarantee of continued success. In order to accomplish this, however, it must be protected by a trademark and a distribution that make it difficult for a competing brand to get into the ultimate consumer's good graces."

It should be noted that, in this case, efficiency has little to do

[3] Manufacturing Engineer, Generating Apparatus Department, Westinghouse Elec. & Mfg. Co., Pittsburgh, Pa.

with the matter, since the monopoly amounts in effect to a subsidy and may enable a small plant to be successful in its own field when it would last but a short time in open competition.

G. F. Gray.[4] The writer wishes to express his appreciation to Mr. Field for his very able presentation of this subject. The writer has recently had occasion to take up the management of a small firm after a number of years in executive work with large ones. Naturally he tried to start the new job by reviewing the experience and conclusions of others as recorded in the technical press. It was quite a shock to find that there was almost nothing in print on the subject. Mr. Field points out that small firms produced half the country's products and constitute 98 per cent of the manufacturing establishments. It is also obvious that their need for business and technical guidance must be greater than that of the large firms. Yet even in the transactions of our own Management Division the percentage of space devoted to their problems bears no reasonable relation to their importance. It seems that Mr. Field's paper is a distinct challenge to us to correct this condition in our own work and to urge others to do likewise. It is generally admitted that the importance of agriculture to the country justifies the unusual efforts which the Government is making in behalf of our farmers. The contribution to general welfare which the small manufacturers make seems no less important, and The American Society of Mechanical Engineers might very well become their spokesman.

The references cited by Mr. Field constitute the best bibliography on this subject that the writer has seen. It might very well furnish the beginning of a complete bibliography to be published by the Management Division.

H. O. Stewart.[5] One of the most perplexing and difficult problems of the manufacturing plant is the efficient control of the non-productive employees. This increases in approximately direct proportion to the number of non-productive operators.

Much has been done in increasing the efficiency of the productive operator. On the other hand, the efficiency of the non-productive operator is scarcely considered at all in the average plant.

Truckers, machine fixers, cleaners, inspectors, repair men, clerks, assistants, etc. set their own pace in most manufacturing plants, notwithstanding the attempts of the supervision to concontrol them, and no matter at how slow a speed they are working it is difficult to give them additional tasks and have them properly handled.

The solution of this problem depends chiefly upon a higher grade of supervision and a reward to the worker based directly upon the results of his efforts. It is, however, almost impossible to measure the results of the efforts of many non-productive operators with sufficient accuracy to set standards of wage payment.

As a result, many compromise methods have been tried. One of the rather common methods used is to pay the non-productive operators in a certain department a bonus which is proportional to the average bonus earned by all the productive operators of that same department.

The weakness of this system is that the reward is not proportional to the individual effort, but is based on the results attained by others. This system is based on the theory that the non-productive operators help the productive operators earn their bonus and that the non-productive operator should be rewarded in proportion to the increase in production over a set amount.

If one non-productive operator out of a group of ten does practically nothing for a week, his bonus would be affected but little, if any. In order to earn the same bonus, the productive operators might have to work somewhat harder or the same result would be attained if the nine non-productive operators speeded up somewhat.

The mental attitude of the non-productive operator is similar to that of great numbers of voters who feel that their votes would have no effect on the outcome of an election consequently, they will make no real effort to register their votes.

The writer believes that the lack of methods of efficiently controlling and properly rewarding the non-productive operator is the chief reason for the great number of small manufacturing plants, and hopes that systems will be devised whereby non-productive operators are rewarded in proportion to the individual results which they attain.

Alonzo Flack.[6] The author's excellent analysis of the problems of management in the small manufacturing plant may well be considered by those interested in the management of large or small manufacturing plants. There is no real reason why some small plants cannot have many of the advantages of the large plant. There are a number of small plants in operation that are perfectly designed for the rapid and economical manufacture of their products.

Labor is a predominate factor in management and takes a great deal of management's attention. Today, however, management is greatly concerned with product, equipment, processes, and methods.

The small plant has the problem of diversification. In some ways to diversify means protection. However, in most small plants many items are continued because the management does not take the trouble to find out that 90 per cent of the sales are made from 10 per cent of the items.

Monopoly, quality, or price are mentioned as the main factors of success. Service is mentioned as a possible factor. Service is a vital factor to the success of most every business.

The operating efficiency of a small plant can be improved just the same as in a large plant if correct fundamental principles are applied.

Author's Closure

The kind reception afforded the paper, and the carefully prepared discussions, whether advocating the author's thesis or opposed to it, have been very much appreciated. Most of the criticism has appended specific examples in which factors other than the fundamental factors mentioned in the paper govern, as will always be the case with individual experiences. It will be necessary, before arriving at a conclusion, however, to study sufficient representative cases to be able to state the most usual trends. Theoretically there is no reason why the very smallest plant cannot be as efficient as the very largest plant, or vice versa, but what we are interested in is not theory but the facts of the case as we may study them.

The favorable reception afforded the introduction of the term "uniquity" to cover all those other factors described, is gratifying, and it is believed that the time is not far off when a numerical scale of uniquity can be adopted and recognized as a yardstick for judging the possibilities in a particular project or existing company.

Measuring Office-Machine Output as a Basis for Wage Incentives

By JOHN MITCHELL,[1] LYNN, MASS.

The author describes the procedure to employ in installing sound standards for office-machine work. After elimination of the unnecessary operations which a study of process sheets reveals, the various jobs are analyzed and the units in which their elements are to be measured are determined. He then takes up the determination of the value of the unit, the basis of payment and method of its calculation, the maintenance of standards set up, etc. An extensive appendix gives time allowances, rates, methods of bonus determination, and other data derived from various sources and covering a wide range of office-machine operations—addressing, typing, tabulating, duplicating, calculating, bookkeeping, etc.

THE general premise that an individual will produce more on an incentive basis than on a straight salary has led to the establishment of plans on an "as is" basis; that is, a betterment of present conditions. To pay the rank and file on such a basis without any study as to the necessity for the work is likely to lead to useless expenditure of money. It is with the knowledge that such conditions exist that the following specific approach is outlined. It can and should be applied to all clerical work, whether it be considered supervisory or routine, mental or manual, or office-machine operation.

This paper is particularly addressed to those at the top who are so busy promoting the enterprise and opening up new avenues for securing profits that they give very little thought to clerical routine, until the expense becomes so heavy that they are absolutely compelled to give it attention.

Clerical work is no longer incidental; it is an important cog in modern industry. Data prepared by the clerical organization become the foundation upon which many executives base important policies. When the typewriter was first placed on the market the consensus of opinion was that it was interesting but superfluous. Many able executives today wave aside with the same words proposals for the installation of sound standards in clerical work. Sound standards are essential for control as well as for forming the basis of wage incentives.

The first step in preparing sound standards is to determine what is to be measured. Output of office machines would naturally suggest itself in view of the title of the present paper. That is only partly true, however, because the actual operating of the machine is usually but a small part of the complete cycle of work performed by the machine operator. There is so much duplication and unnecessary work done in an office that it would not be fair to set a standard without taking into consideration the whole situation. It is therefore necessary to consider the flow of work for the entire department and organization.

Process Chart Eliminates Unnecessary Study

The process chart, a simple but efficient tool of management, was devised by Frank B. and Lillian M. Gilbreth.[2] A simple process chart showing the travel of each type of order or document from the time it is received or started until it reaches its final destination should be prepared. These charts should not only reflect the flow of work through a department, but also through the organization. They should cover every method and record in the office.

A careful analysis of these charts will disclose unnecessary and duplicate documents and operations. It may mean rearrangement of departmental set-ups to eliminate duplication of documents and operations, but this should be done wherever possible. The changes will save a great deal of study and will eliminate conditions which if allowed to exist might form a weak foundation for a wage-incentive plan.

After the unnecessary work has been eliminated, it is essential to review the work performed by each individual or "job." The best procedure for obtaining such data is through a job analysis.

Job Analyses Will Determine the Component Elements of Jobs

Harry A. Hopf, of H. A. Hopf & Co., in his paper "Improving Management Through Job Analysis," presented at the A.M.A. winter convention in 1927, defined job analysis as "that process which results in establishing the component elements of a job and ascertaining the human qualifications necessary for its successful performance." There is considerable literature available on the subject, and therefore it is not essential to dwell upon the details here. However, "establishing the component elements of a job" is the result that should be obtained to assist in the determination of what is to be measured.

What Is to Be Measured

It is extremely important to know these "elements," if they have not already been reduced to writing. Do not depend upon your knowledge or that of the supervisor of the particular job. Too often there is a wide difference between what is "supposed" to be done and what is actually done.

A careful study of the job "elements" disclosed by job analysis will point out many that can be eliminated, combined, or performed in a simpler manner. The following example will illustrate the importance of this statement.

In a typing bureau the typists inserted and withdrew the carbon paper in connection with their work, and a wage-incentive plan had been established on the basis of the number of lines typed. The typists found that the average number of sheets of typed material for each set-up was so great that the insertion and withdrawal of carbon paper represented about 20 per cent of their time. They persuaded the messenger or clerk to insert and withdraw the carbon. Their earnings were thus automatically increased by utilizing the released time for productive work.

A supervisor would have real difficulty in determining what portion of the original set-up was represented by the handling of carbon paper. A job analysis, however, would have disclosed the condition, and it would have been considered and recorded in preparing the basis for evaluating the "line." If it was not separated until after the incentive had been in operation for some time, the record would still show the valuation placed upon

---

Presented at the National Management Congress, Chicago, Ill., March 5 to 7, 1930.

it. This would enable the separation to be made at any time on a fair basis.

Up to this point the author has dealt with the tearing apart of existing conditions, eliminating obvious wasted effort, and with what is to be done. The next step is to determine the unit of work that is to be measured. (Examples of specific cases are given later in the form of an appendix.)

Determination of Unit to Be Measured

With the component elements recorded, it is then possible to review them carefully to see what combinations, if any, should be made. This study should be made having regard to the size of the organization, department, or group in which the work is to be performed, and to the difficulties that will be encountered in making changes.

Measurement is the beginning of all science, but no scientist ever said that everything could be weighed, counted, or measured by a yardstick. There are different methods of measuring. It is not always possible to select, at once, a unit that will be thoroughly satisfactory. There are many things that cannot be measured, but, on the other hand, there are many that can. The greatest difficulty is to convince executives that there is some way of measuring some part of the work.

The majority of executives allow the affairs of their respective organizations to be dominated by the considerations which controlled their points of view in the specialized lines to which they devoted their energies while in subordinate positions. This condition is even more aggravated in the case of clerical work. A good salesman will be promoted to be sales manager and will be in charge of the clerical work pertaining to sales. A designing engineer will become a managing engineer and have charge of clerks in that department. It goes on in all lines even down to the general foreman in a manufacturing department who will be in charge of the clerial work affecting his department; he is primarily interested in producing product, so clerical work is incidental with him.

Modern office machinery, like manufacturing machinery, should not be permitted to remain idle if it is possible to keep it in profitable operation. This should be uppermost in the minds of those who are determining the unit to be measured. For example, a job analysis of the clerical work in an order department might disclose the fact that customers' orders are read and the contents modified to factory or warehouse requirements by the reader; orders are then typed in hectograph in accordance with the modified copy; copies of the orders are made on duplicating machines; the sales or some other value is figured by calculating-machine operators; records for statistical purposes are compiled by hand and later summarized in report form by typists; and correspondence with customers and internal departments dictated to stenographers. The work will likely be given to those who are in a position to do it. A stenographer may type reports, use the calculating machine, and be an able clerk.

The department may be under an efficient manager who is producing results. He is anxious to reward his staff and encourage them to produce more. A wage incentive is proposed. It is difficult to measure the work of the individual, so it is decided to take the group as a whole and use the order as a unit. The plan is started. The clerks produce more and earn more. The manager receives praise from his chief executive. Everybody is happy.

What is done about the typewriters and calculating machines that are idle a goodly portion of the time? Why do statistical work by hand that can be performed more economically by machine? Why dictate to a stenographer when dictating machines are available? Of course, the stenographer is carefully labeled in the job analysis as "doing other work; dictation is only a small part of her job." The latter is a stock argument against the use of central transcribing bureaus.

Suppose that the job analyst had a broad experience and is not tied by politics and petty jealousies his report would read somewhat as follows:

Typewriting:

Order Department	.....hours
Sales Department	.....hours
.....	.....
.....	.....
.....	.....
	.....
Total Typing	.....
	.....

Note: It is possible to use continuous forms on certain orders and sales work. A typewriter adapted to these forms can be used, thus eliminating insertion of carbon and the tie-up of investment in more than one machine. Reports that are difficult to prepare can be handled by a specialist and produced in a fraction of the time taken by a stenographer. Recommend that all of the above typing be placed in a central bureau.

Duplicating Machines:

Order Department	.....hours	.....machines
Sales Department	.....hours	.....machines
Accounting Department	.....hours	.....machines
.....	.....	.....
.....	.....	.....
Total Duplicating	.....	

Note: The cost of duplicator rolls represents a comparatively large item of expense in this work. Proper use and care of rolls can be obtained only through careful supervision. It is therefore recommended that the above work be centralized and the investment in machines and expense in rolls materially reduced.

Calculating:

Order Department	.....hours	.....machines
Sales Department	.....hours	.....
Accounting Department	.....hours	.....
.....	.....	.....
.....	.....	.....
	.....	.....
Total Calculating	.....	

Note: It is recommended that all of the above work be performed in a calculating bureau. This will permit the employment of experienced operators and reduce the investment in machines.

Statistical Machines:

Statistical work performed by hand in the following departments, if centralized, will permit the purchase and profitable use of..... statistical equipment. (The order department is included.)

Dictating Machines:

An analysis of the dictation by the correspondents in the order department discloses the fact that a large portion can be carried on by means of form letters. The remainder of the dictation and the fill-in data required on the form letters can be given to dictating machines at a much greater speed than to stenographers.

To produce the best results, it is recommended that the transcribing be done in a central bureau.

As the operations of the calculating, statistical, duplicating, typing, and transcribing bureaus are closely related, they should be physically located together so that there will be no unnecessary travel. An adequate messenger service will be maintained between departments. A definite schedule on all work will be maintained, thus providing means of knowing when work will be done.

These bureaus, the messenger service, and machine maintenance will be under the supervision of the office manager.

What is left in the Order Department? The order readers and a greatly reduced staff of correspondents. The order is still the unit of measurement, but there is a great difference in the value given to it. It can be more easily evaluated. The

miscellaneous clerical, typing, and stenographic work which would cause difficulty in the original set-up have been removed and put in a place where they in turn can be easily measured.

What will the Order Department manager and other department managers do? Will they say to the chief executive, "We recognize the advantage of efficient use of modern office machinery; we believe that the centralization of such machinery will keep it in productive use more continuously than if it were scattered throughout our departments, and will reduce the investment and maintenance expense; it will also be possible to use experienced operators who will be continuously employed on one type of machine, thereby making it possible to measure their output either on an individual or group basis?" No. Each one will have at least a hundred reasons why it cannot be done to every one he will give for doing it. Then, as chief executive, what are you doing to do? If you were a specialist before rising to your present position, you will immediately go over the story as it relates to that department. You will confirm the present department head's objections. Then, expressing a desire to be impartial, you go to the end of the report and there you see the words "Office Manager," and you say: "Ah, who is this? What does he know about our business?" Then you call for the job analyst.

If, as already stated, the job analyst is a broad-gaged individual, he will have his handbook of standard questions and answers with him. You ask him, "What does an office manager know about our business?" He turns to Question 21 and finds the answer: "An office manager should know the best equipment for performing any particular type of clerical work; he should be able to secure the greatest output in quality and quantity from such equipment; and be able to translate requests for data pertaining to the particular business in which he is engaged into machine-hours; and produce the results requested. In other words, he does what he is told to do in the best, quickest, and most economical manner."

You then ask, "How and where can we get such a man." He turns to Question 22: "Ask W. H. Leffingwell; he will tell you all about the procurement and training of an office manager." The job analyst sticks to his story, and the result of his work will be a success or a failure depending upon whether you will face the facts and use them or judge in accordance with past experience supplemented by the prejudiced, personal opinions of your department heads. Fortunate is the organization whose executives and supervisors are willing to make impartial decisions based upon facts.

Where there is a large volume of the same type of work performed by a large staff of machine operators, such as public-utility billing, where the unit would be the "bill," it is comparatively easy to determine the unit. Where there is a variety of operations performed in a department by a number of clerks who are not confined to any one particular operation, the principal document should be considered the unit, and all subsidiary papers tied up to it. For example, the order would be satisfactory in an order department. It would be necessary to determine all the work pertaining to the order in the particular department and make allowance for orders requiring special treatment. It might be necessary to divide the orders into several classes and give a value to each class. In a shipping department, the memorandum of shipment or bill to the customer would be the unit. Again it might be necessary to divide shipments into classes such as freight, express, and parcel post. Each of these classes requires varying additional documents, and would therefore have a separate value. The work of an individual or group of individuals may be tied up to any of these units.

In centralized departments where office machinery predominates, it is usually customary to use the unit produced. For example:

Addressing Machines—Number of stencils or plates of certain number of lines, number of impressions produced
Tabulating Equipment—Number of cards and holes per card
Typewriting—Number of lines, square inches, letters, reports, or cyclometer points are used
Duplicating Machines—Number of copies produced. Where the setting up of the machine is a large factor and the copies are made automatically, the set-up is the principal unit while the running time is incidental.
Calculating Machines—Number of documents. Each type of recurring document will have on an average the same number of calculations. Therefore it should be possible to place a value on each class of document
Bookkeeping Machines—Number of entries or documents posted.

For definite data and experience of others in determining units, reference should be made to Appendix No. 1

How the Value of the Unit Should Be Determined

In setting a value or making a standard upon which to base a wage incentive plan, it is well to consider the subject under two factors, quantity and quality.

Quantity. To determine the quantity, the unit should be counted, and the time consumed in handling it should also be calculated. The count should extend over a period long enough to bring in the principal variations in volume. The overall time consumed in handling these units during the period should be recorded. This is for a general guide only.

A time study should be made. The minuteness of the study should be determined by the volume of units and number of persons involved. In all cases, the elements involved in a unit should be time-studied separately. The time for each unit should be fair. It should take into consideration unavoidable delays, personal time out, and uncontrollable conditions. It should represent what is to be expected from a good grade of clerk.

In cases where several clerks are performing the same operation, it would be profitable to make a micromotion analysis of the work. This will enable the analyst to eliminate waste motion before setting the time factor.

Quality. Too often wage incentives are given on output without considering quality. Quality must be determined and carefully set forth in writing before starting any plan. It may mean the performance of work within a definite schedule, the reduction of errors, or some factor which will prevent carelessness or unnecessary expense in the group or some other group. For example, in the case of a purchasing department, quality factors may be listed as follows:

(1) Reduction in ratio of transportation cost to cost of incoming material.

(2) Meeting "wanted" dates set by the factory.

(3) Reduction in telephone, telegraph, and correspondence expense.

It will be noted that to meet factor (1) there will be an inclination to extend the "wanted" dates so that all deliveries can be made by freight. To meet factors (1) and (2) there will be an inclination to increase factor (3) by telephoning, etc. By carefully weighing each of these and other factors in determining the value of the unit, which in this case is the purchase order, it is possible to set a fair standard.

Each standard must fit the particular conditions under which it is to operate. The total situation must always be kept in mind so that one group will not earn a bonus at the expense of another group. A clear definition of the standard should be written so that any modifications can be made and the values fairly adjusted.

What the Basis of Payment Should Be

There are several bases for payment which should be carefully considered before deciding upon a plan.

Individual. Payment on the output of the individual is very common in the case of office-machine operators. In large organizations where there are groups of specialists, it may be advantageous. The appeal to the individual may cause him or her to produce more. The clerical expense in keeping records of output and payment is greater than under any other basis.

Group. Determining the standard on the basis of the group is becoming popular. It requires less clerical expense than the individual plan. Care should be taken to see that there is a community interest in the group, otherwise it will be hard for the members to see their part in reaching the objective.

This base is best adapted to conditions where the exact measurement for each unit is difficult to obtain or exorbitant to maintain.

Supervisor. The payment of a percentage of the salary of the immediate supervisor of a group for each per cent that he reduces the expense below a predetermined amount under a predetermined schedule of conditions or service.

For example, assume that a supervisor receiving $60 a week controls a unit incurring $1200 a week expense. If we give 1 per cent for every 1 per cent he reduces his expenses while maintaining a definite schedule of service, the result of a 10 per cent reduction in expenses would be: Salary, $60 + 10 per cent = $66. Expenses, $1200; reduction of 10 per cent = $120. Therefore by paying $6, we would obtain a net saving of $114.

Such a plan should be reviewed annually and the standards adjusted to current conditions. To those who do not wish to spend the money or time to make the complete study recommended, this plan may help as a preliminary. Later when apparently rock bottom has been reached, the study should be made and a sound incentive plan established for the group.

Method of Calculating Payment

There are a number of thoroughly tested plans, such as the Bedaux, Gantt, Rowan, Emerson, etc., which can be used. These are all described in the "Management Handbook" and in other publications. The choice should depend upon which one, in the opinion of the individual doing the work, will produce the best results.

Who Should Set the Standards

Too often the task of setting standards is placed in the hands of a junior in the time-study department, if one exists, or if not, in those of a bright young clerk, who has neither the qualifications nor the experience required.

The work as outlined requires the services of a job analyst, whose qualifications will be found in any literature on the subject of job analysis. If you have such an individual in your organization promote him to a staff position, as assistant to an executive who can and will give the analyst the necessary backing when required.

Perhaps the most economical plan is to engage the services of a managment engineer of good repute. His impartial point of view will be refreshing to the wide-awake executive and will more than offset any lack of inside knowledge of the particular organization. His recommendations may be radical, but the executive who follows them will find them to result in lasting saving effects.

Maintenance of Standards

It is wise to recognize that the idea of perfection is not involved in standardization. The standard method of doing anything is simply the best method that can be devised at the time the standard is established. Improvements in standards should be solicited and adopted whenever they are found. But to protect standards from changes that are not in the direction of improvement, certain safeguards must be provided. These safeguards protect standards from change for the sake of change. Among them are:

1 All standards must be carefully defined and described in writing
2 Any proposed change must be carefully scrutinized by those who framed the standard
3 Any change must be approved by the supervisor in charge
4 The changed standard, carefully defined and described in writing, must be followed.

Conclusion

A careful adherence to the foregoing program will provide real data for establishing and maintaining a sound wage-incentive plan. It will encourage "permanent prosperity" and give the organizations adopting it permanent reductions in expense.

Actual plans now in use, and which have resulted in large savings, are given in the Appendix. Its perusal is recommended, and if from it or from any other part of this paper a single executive finds assistance in solving his problems, the author will feel that his labor in preparing it has been well repaid.

Appendix No. 1

EXHIBIT I

At present we have the following operations on office equipment on a bonus basis:

Punching and Verifying Tabulating Cards (Hollerith). Time allowance is set per card. Some of the rates are:

0.0025 hr. per 20-hole card
0.0031 hr. per 30-hole card
0.0045 hr. per 45-hole card.

Employee brings cards punched to supervisor, who marks the task symbol on the time card. Timekeeper weighs the punched cards, converting weight into number of cards by multiplying weight in ounces by 11.8. Number of cards multiplied by task equals the time allowed. Employee receives 20 per cent of the time allowed as a bonus, provided the time allowed is not less than the time taken.

Example:

Employee punched 1 lb. 10 oz. of 30-hole cards.
26 oz. × 11.8 cards per ounce = 307 cards
307 cards × 0.0031 hr. = 1.0 hr. time allowed
20 per cent of 1.0 hr. = 0.2 hr., + 1.0 hr. = 1.2 hr.
Employee receives pay for 1.2 hr. while time taken was 0.9 hr.

Sorting Tabulating Cards. Time allowance is set per card. Rates are:

0.0035 hr. per card for less than 1000 sorted
0.0033 hr. per card for more than 1000 sorted.

Number of cards sorted is obtained by automatic counter on sorting machine.

Method of paying employee is identical with that for punching cards.

Invoicing. The time allowance for invoicing is based upon the Underwood fanfold typewriter. Four copies (original and three duplicates) are made. This type of invoicing is for goods being issued from the manufacturing operations to finished goods. Entries typed on invoice are invoice number at top, commission (4-digit), color (4-digit), piece number (2-5 digit), and yards (3-digit).

Time allowance:

0.016 hr. per invoice
0.0025 hr. per piece.

Production is counted by the timekeeper from a copy of the invoice. Bonus payment is based upon the size of job, that is, time

allowed divided by time taken equals the size of job. Payment of bonus is made on the clerical scale—10 per cent payment for 80 per cent job, and 0.5 per cent for each 1 per cent increase in size of job.

Typing. Although we have a time allowance for straight typing, we are not at present paying bonus.

The time allowances are:

0.0046 hr. per 6-in. line typed from copy
0.0053 hr. per 6-in. line typed from notes
0.0038 hr. per sheet if carbon copies are made
0.0067 hr. per page regardless of number of copies.

NOTE: Per sheet includes inserting and removing carbons; per page includes putting in and removing sheets from machine.

Addressographing. Time allowance for addressographing regular tabulating cards $3^1/_4$ in. × $7^3/_8$ in.:

0.435 hr. per job (this is allowed for each time the job is completed.)
0.00054 hr. per name per card addressographed.

Employee enters the job symbol and the number of cards addressographed on his production card. These entries are checked, to the order for the material, by the supervisor.

The time allowed is figured by multiplying the number of cards addressographed by the rate per card and adding the job allowance. Employee is paid bonus of 20 per cent of time allowed, as explained under Punching and Verifying Tabulating Cards, if the time allowed is not less than the time taken.

Multigraphing. Time allowance for multigraphing paper $8^1/_2$ in. × 11 in. of 13-lb. to 50-lb. weights. The rate includes placing the plate on the machine, inking, adjusting plate, running time, etc.

0.07 hr. per job
0.00025 hr. per sheet.

Employee enters the job symbol and the number of sheets multigraphed on his production card. These entries are checked, to the order for the material, by the supervisor.

Time allowed is figured and bonus payment made in exactly the same manner as described for addressographing.

Machine Calculations. The task for work on calculating machines is incorporated with other studies, and employee is paid a bonus according to the size of job accomplished.

EXHIBIT II

All of our graphotype work is done on bonus. A standard model G-3-D machine is used. The work includes receiving sheets with the necessary information, punching the name, address, policy number, agency symbol, premium-due date, and sometimes the amount of the premium. The information is put on three small plates which are fitted into one frame. When changes are made, usually only one of the three plates is punched anew. The allowance for punching a stencil without the premium amount is 1.05 min., and with the premium amount, 1.16 min. As the premium amount is punched on about 80 per cent of the stencils, the hourly output would be about 53 stencils. The average allowance for making changes is 0.400 min., and the output would be 150 per hour.

The punch operators in the Hollerith Division are working on bonus and are using the model 20 electrified machine. The work includes receiving information sheets, punching cards, and returning the work to the supervisor. The average allowance is 0.220 min. per card punched. This would give an hourly output of 273 cards.

In all of the divisions a daily record is kept of the number of various types of items handled by each person. This is usually the duty of the supervisor, and does not make additional personnel necessary, He also keeps a careful record of all time not spent on bonus work, keeping absent time, time spent on non-bonus work, and free time separate. Forms are provided for this. The bonus is figured and paid twice a month.

The basis on which bonus is paid is the percentage of efficiency, which is obtained by dividing the total minutes credited by the total minutes spent on bonus time. The clerk's credit is from two sources —number of units produced multiplied by rate in minutes per unit, and a standard allowance per session for personal time, cleaning machines, getting supplies, etc. The actual bonus time is the number of minutes in the period less minutes not spent on bonus. If the percentage of efficiency is above 70 per cent, the clerk is entitled to such percentage of her salary in bonus as her efficiency exceeds 70 per cent; that is, 85 per cent efficiency gives a clerk in bonus 15 per cent of her salary for the time worked. A typical bonus calculation would be as follows:

Minutes credit for production	3400		
Minutes credit for standard allowance	340		
Total minutes credit	3740	$\frac{3740}{4400}$ = 85%	efficiency
Total minutes in period	4500		
Minutes deducted	100	Less 70	
Total minutes bonus time	4400	15% bonus	

(Salary per minute)	×	(Minutes bonus time)	×	(Per cent of bonus)	= bonus amount
0.007575	×	4400	×	0.150	= $5.00

Penalty for errors may be a deduction from the bonus money earned, the amount per error being enough to make the clerk feel his loss through inaccuracy; or the penalty may be a loss of units of work on which credit is based. It has been our experience that the bonus ultimately increases accuracy.

An organization working at ordinary efficiency can expect about a 30 per cent reduction in personnel by the installation of a bonus.

Additional benefits of the bonus system are (1) a complete record of what each clerk is doing; (2) a tangible recognition of a clerk's superiority which cannot be considered in the regular salary; (3) longer service and greater income for the better employees, and the elimination of the poorer ones, as the aggregate saving of time enables us to decrease the staff; and (4) greater ease of supervision.

EXHIBIT III

We have measured output and pay and an incentive wage on billing-, calculating-, and typewriting-machine operations as they are used in the billing division of the customers' accounts departments.

Billing Operations

Machines Used: 27 style 2700 Burroughs public-utility billing machine (16 bank)
2 style 131700 Burroughs public-utility billing machine (17 bank)
(The latter machines are used for accounts which require a greater totalizing capacity, but otherwise are essentially the same as the larger group.)

Unit of Measurement: One complete bill.

Standard of Production: 270 units per hour, which is rated as 100 per cent production.

Operators must attain the standard production of 270 units per hour or 100 per cent before the wage incentive is applied.

For each per cent attained over the standard, the operator receives as an incentive wage 1 per cent of her hourly rate earned as regular salary. To illustrate:

Employee's salary per month	$120.00

Hours to earn above, assuming a 30-day month with 4 Saturdays and 4 Sundays:

22 days of 7 hours	154 hours
4 days (Saturdays) of $4^1/_2$ hr.	18 hours
Total	172 hours
Rate per hour = $120 ÷ 172 =	$0.697
Actual hours worked	80
Standard hours allowed	90
Efficiency 90 ÷ 80 =	113%
Percentage of bonus for 113% efficiency	13%
Total wages for actual hours 80 × 0.697	$55.76
Incentive wage, $55.76 × 13 per cent	$ 8.25

Incentive wages are paid for work done on standard operations only. In the example the employee worked 80 hours on standard work; therefore the bonus is for 80 hours' production. Had she attained the same production for the entire month the incentive wage would be $15.60 and total earnings $135.60. Total earnings in example shown would be $128.25.

The example illustrates how the gross bonus is computed. A deduction is made for errors based on a sliding scale as follows:

Less than one (1%) per cent of error	$^1/_2$¢ per error
1 to 2% of error	1¢ per error
2 to 3 per cent of error	$1^1/_2$¢ per error
3 to 4% of error	2¢ per error
4 to 5% of error	3¢ per error
Over 5% of error	5¢ per error

Our billing operation calls for the production of approximately 900,000 bills per month. Before the introduction of the wage-in-

centive plan the average output for all operators was about 180 bills per hour with 35 operators employed. At the present time the average production for all operators is approximately 305 bills per hour with 21 operators employed.

Errors average less than 1.2 per cent per operator, while the average bonus is 13 per cent.

The average individual range of attainment for a monthly period is between a high of 166 per cent and a low of 65 per cent.

The operator making the low attainment of 65 per cent is classified as a student having been on the work only a short time.

We have two operators, who seem to be exceptionally adept at the work, both of whom average from month to month 160 per cent of the standard.

Production for the larger number in the group varies between 102 and 140 per cent of the standard.

Operators who cannot attain the set standard of 270 bills per hour, are, after a fair trial, either transferred to other work or discharged.

Calculating. This work consists of proving the results of the billing operation. It is primarily addition and the application of a formula to prove that the proper rates have been applied to the customers' bills. In effect two operations are included:

(*a*) Balancing bill register sheets
(*b*) Checking bills.

The standard applies to the combined operation.

Machine Used: Felt and Tarrant comptometer (8 bank).

Unit of Measurement: One bill (the same unit is used for all operations.)

Production Standard: (*a-b*) Combination operation, 625 bills per hour.

The incentive wage is computed in the same manner as outlined above for billing operations. This group handles the entire output of the billers, that is, approximately 900,000 bills per month, with the attendant register sheets. The introduction of the incentive wage has resulted in an increase in the average production from 104 to 121 per cent of the standard. Operators have decreased from 13 to 11.

Graphotyping. Work consists of making addressograph plates showing customer's name, address, and other information.

Machine Used: Addressograph Co. No. G3-keyboard graphotype.

Unit of Measurement: Embossing 1 complete plate.

Production Standard: 90 plates per hour.

The incentive wage is computed in the same manner as outlined above for billing operations.

The volume of work involved in this operation is approximately 350,000 plates per year.

There were four employees in the group before the introduction of the incentive-wage plan. Since that time production has increased from 92 to 115 per cent of the standard and the number of employees has been reduced to three.

EXHIBIT IV

1 *Billing Work.* Royal typewriting machines with special character keys are used. 50,000 key strokes per operator for an eight-hour day is considered 100 per cent of efficiency in performing this work. We use a Veeder-Root Cyclometer on our machines to record the number of key depressions made by each operator each day.

2 *Multigraph Work.* We use a Set-O-Type machine manufactured by the Typographic Machines Company, of Dayton, Ohio, to set up the type used in running the letters on the multigraph machine. The standard time that we have established on this work is 0.319 min. per line of type set and a constant time per letter of 5.50 min.

Multigraph Printing (Machine Model No. 36). We have both the hand-fed machines and automatically fed machines in operation. The standard time per sheet on the hand-fed machine is 0.0132 min., with a constant per order of 3.76 min. The standard time on the automatically fed machine is 0.0151 min. per sheet, with a constant of 3.76 min. per order. The time on the automatic machine is slightly more per sheet, yet of course it does not require the attention of an operator to keep it going, so that the saving in labor resulting from the use of an automatic machine is considerable.

3 *Mimeograph Work.* We use a model No. 78 Mimeograph machine for performing our mimeograph work. In establishing standards for the running of this work we have classified the work into two groups, one where the machine automatically inserts a blotter between each two sheets of material run, and the other where blotters are not used at all. The standard times for the first classification where the blotters are automatically inserted by the machine are:

1st speed of machine	0.0734 min. per sheet
2nd speed of machine	0.0685 min. per sheet
Constant time per order	5.50 min.

The standard times for the second classification where blotters are not used at all are:

1st speed of machine	0.0392 min. per sheet
2nd speed of machine	0.0344 min. per sheet
3rd speed of machine	0.0305 min. per sheet

The constant time per order is 5.12 min. We have a standard on each of the three different speeds inasmuch as it is found that certain classes of work can be run at a faster speed than can others.

4 *Cutting Manila Stencils.* We use a Royal typewriting machine in cutting these stencils. This machine is a regularly equipped correspondence machine. We have two different classifications of this work, one where the address is composed of three lines without a code number, and the standard time for this class of work is 0.517 min. per stencil. The other class of work is identical with the first, with the exception that there is a code number composed of four digits which is placed at the left-hand corner of the stencil but on the same line with the city or state. The standard time for cutting a stencil of this classification is 0.550 min. The above times include the wetting of the stencils previous to inserting them into the machine for cutting.

5 *Addressing-Machine Work.* We use machines made by the Elliott Addressing Machine Company. These machines are hand-fed. Several different kinds of work pass through these machines, but the greater portion of it is 6 × 9-in. envelopes. The standard time allowed for addressing each envelope is 0.0383 min., with a constant per order of 2.53 min. We use these machines also to fill in doctors' names and addresses on certain detail slips that we send to salesmen. These slips are approximately 3 × 5 in. in size and are made up three in a group. The standard time for addressing these slips is 0.0498 min. per slip, with the same constant per order as indicated above.

6 *Key-Punching Work.* We use an electric key-punching machine manufactured by the International Business Machines Corporation. This machine is used to indicate the amount of sales made by each salesman to each of the customers called upon. These sales are represented by figures of four digits. The standard time that we allow for the automatic key-punching operation is 0.08661 min. per order, which represents one punched card. We use a master-control card in which is punched the territory number, salesman's number, and certain other miscellaneous information. This card of course controls the information that is automatically punched in cards that are run through this machine. The standard time allowed for punching the master control card is 0.1468 min.

7 *Posting Work.* We use a Dalton Multiplex machine in keeping a record of the amounts represented by the orders taken by our salesmen. The amount of each sale is posted on an individual card set up for each customer. The figures posted are composed of either three or four digits. The posting operation includes picking up the previous total, posting the amount representing the sale made, broken down into two parts, and then showing a new total on the sheet. The standard time for this operation is 0.240 min. per card posted.

8 *Typing Letters and Envelopes.* We use regular Royal typewriting machines in performing this work. There are several classifications of this work, one of which is copying letters of solid type on the regular letter-size forms, $8^1/_2 \times 11$ in. The standard time for performing this work is 0.2851 min. per line. 1 minute extra per letter is allowed if a carbon copy is required.

Addressing Envelopes: The standard time for addressing envelopes is 0.4277 min. per envelope, and the time for addressing postal cards is 0.5861 min. per card.

EXHIBIT V

The following bonus plan for key-punch operators was adopted after months of close study of past production records, and from time-study tests made with various operators for various periods.

A base salary is paid to all operators as follows:

$15 per week for beginners until they reach an output of 2800 cards per day
$16 per week for 2800 cards
$18 per week for 3000 cards.

After an operator reaches an average daily production of 3000 cards, with 1 per cent of error or less, she is paid 10 cents per 100 cards for all cards in excess of 3000.

Operators are given preference according to their production record. That is, No. 1 operator is given the first chance for continuous em-

ployment on card punching. This creates a competitive spirit among the operators. Those not engaged on card punching are paid the base salary only.

Errors. Deductions for errors are made at the rate of 2 cents each for all in excess of 1 per cent. No deductions are made from base pay. As a matter of fact, skilled operators average about three-fourths of 1 per cent, and deductions are seldom made except during the period when operators have reached the 3000-cards-per-day stage and have not yet attained the skill necessary to maintain higher production.

It should be mentioned here that our experience proves that increased accuracy and increased production on this kind of work run hand in hand. As production goes up, accuracy increases, or perhaps as accuracy increases, production goes up.

When the plan was started production of our best operators was about 3900 cards per day. Since the plan has been in operation, production has increased to as high as 5500 and 5700 cards per day for one week. This latter figure, however, was discouraged by the management, as it was noticed the operators were under a severe physical strain when working at this pressure. The average production today for our best operators is about 5500 cards. This is equivalent to a bonus of $2.50 in addition to the base pay of $3.00 per day.

The principal advantages of this plan are as follows:

1 Compensation based on actual production, resulting in better satisfied employees, as amount of earnings is limited only by inclination and skill of operators.

2 Provides an interest in the work due to competitive spirit developed.

3 Greater production at lowered unit cost.

4 Reduces training expense of new operators due to decreased turnover.

5 Improves attendance records as absence reduces earning power.

6 Production is more uniform as there is constant incentive for greater production.

7 Aid to office management.

Additional Aids to Production. At the same time the bonus plan was introduced, the electric key-punch machine was also adopted. This machine is doubtless entitled to some credit for increased production. The manufacturers claim 10 per cent increase in production. As our gross increase is about 40 per cent, we credit the bonus plan with an increase of 30 per cent.

Comptometer Operators' Incentive Plan. About two years ago we were faced with the problem of obtaining greater production from our comptometer operators on a certain class of work. We had been experimenting on various methods of getting increased output. Production and error records for each worker had been maintained and published in the hope that these would inspire the operators to greater effort.

Based on these records, flat salary increases had been made within certain broad production ranges. However, it was observed that while periodic salary increases had an immediate effect on increased production, the increased production was not maintained. This seemed to prove that the flat salary plan did not provide a sufficient incentive to constant high production.

After careful study, which incidentally had been going on for a period of two years, we worked out what we felt was a satisfactory day's production and for which we were willing to pay $3. This daily rate has no bearing whatever on the wage rates existing in this city. It is merely a base on which to calculate earnings for production in excess of the required minimum.

Our plan calls for a minimum production of 10,300 items per eight-hour day. No deduction is made for failure to reach this figure as it is not a difficult goal to attain. It usually takes a beginner three or four months to reach this production.

As soon as an operator maintains this rate of production for a period of two weeks, she is placed on the flat base rate of $3 per day. In addition she is paid $0.0341 per hundred items for all in excess of 10,300 per day.

A deduction of 2 cents each is made for all errors in excess of 1 per cent. By making a rather liberal allowance for errors, much clerical accounting work is avoided.

This plan has been in use for over two years and has been very successful. Production has increased from a daily average of 13,300 items for all operators to the present figure of 19,000 items per day for all operators.

Prior to introduction the daily average of our best operator was 6724 per day and the present average per day for the best operator is 20,000 items per day.

The error rate is now 0.446 items per 100, or considerably less than half what it was formerly.

It is our belief after trying both methods of production control that far better results in every way will be obtained from a good incentive plan than can be secured with the very best kind of "supervised" production, and with much less expense on the part of the management. Our supervision is almost automatic.

EXHIBIT VI

Comparison of Salary and Incentive Plans as Used in the Customers' Accounts Division

Graphotype. Until May, 1925, our graphotype operators were on a salary basis of approximately $25 per week. The monthly average of plates embossed per operator was approximately 7000. In June, 1925, the incentive plan was inaugurated with the following immediate results. The June figure showed an increase in plates embossed to approximately 8000 per operator, with an error percentage of 4.8 per cent and a wage scale of $24 per week. The July, 1925, figure showed a further increase in plates embossed to approximately 8500 per operator with an error percentage of 5.5 per cent and a wage scale of $25 per week. It will of course be understood that the wage scale is based on the number of plates embossed and the number of errors. Our error percentage showed a sharp decrease from this point on, while the average number of plates embossed per operator increased. Our figures at the present time, and these figures are just average, show approximately 9500 plates embossed per operator per month, with an error percentage of approximately 1.5 per cent and a weekly wage scale of $27.

The following figures reflect the yearly saving made by the introduction of the incentive plan:

Salary Plan

Plates embossed (number embossed in 1929)	310,000
Percentage of errors	5
Total labor cost	$5,096.00
Labor cost per 100 plates	$1.64

Incentive Plan

Plates embossed	310,000
Percentage of errors	1.5
Total labor cost	$3,741.00
Labor cost per 100 plates	$1.21

It is interesting to note the drop in percentage of errors, and also that the saving in labor cost is approximately 27 per cent.

Billing. The incentive plan has been in effect in our billing room about 10 years. This plan when first introduced paid a maximum of $27 per week. Since that time the maximum wage has been increased to $35 per week. Comparative figures are herewith given, showing the pre-incentive figures as compared with the present figures.

Pre-Incentive Plan

Number of bills rendered	1,385,791
Percentage of errors	4
Total labor cost	$29,900.00
Labor cost per 100 bills	$2.16

Incentive Plan

Number of bills rendered	2,626,330
Percentage of errors	1.3
Total labor cost	$42,660.00
Labor cost per 100 bills	$1.62

The incentive plan, as usual, resulted in a decrease of the number of errors and in a 30 per cent saving in labor cost. Before its adoption the number of bills rendered per hour was 53; after adoption the number was 99.

GRAPHOTYPE PLATE-EMBOSSING WAGE SCHEDULE

(General Accounting Department, Customers' Accounts Division)
Effective June 1, 1925

Points per month	Wage per week	Points per month	Wage per week
5000	$18.00	10,000	$28.00
6000	20.00	10,500	29.00
6500	21.00	11,000	30.00
7000	22.00	11,500	31.00
7500	23.00	12,000	32.00
8000	24.00	12,500	33.00
8500	25.00	13,000	34.00
9000	26.00	13,500	35.00
9500	27.00		

(*a*) Embossing of three-line plates to be counted as one point for each plate.

(*b*) Embossing of four- or five-line plates to be counted as one and one-half points for each plate.

The number of errors are to be taken into account and to be deducted from operators' total points according to the following schedule.

No. 1—Errors made on three-line plates: Deduct five points for each plate.

No. 2—Errors made on four- or five-line plates: Deduct ten points for each plate.

Wage rates to be adjusted monthly and to be effective the second Monday of each month.

Agreed that if the 400- or 900-mark is passed, the nearest even figures of scale will be allowed.

ELLIOTT-FISHER MACHINE-BILLING WAGE SCHEDULE

(General Accounting Department, Customers' Accounts Division)
Effective March billing, 1925

Points per month	Wage per week	Points per month	Wage per week
6,500	$20.00	10,500	$29.00
7,000	21.00	11,000	30.00
7,500	22.00	11,500	31.00
8,000	23.00	12,000	32.00
8,500	25.00	12,500	33.00
9,000	26.00	13,000	34.00
9,500	27.00	13,500	35.00
10,000	28.00		

The number of errors are to be taken into account and to be deducted from operators' total points according to the following schedule:

No. 1 Class of Error. Billing on wrong billheads or ledger records: Deduct 250 points for each error. Failure to clear machine, duplicate billing and incorrect subtraction: Deduct 100 points for each error.

No. 2 Class of Error. Incorrect totals on bottom of balance sheets: Deduct 50 points for each error.

No. 3 Class of Error. Writing over figures and failure to type in headings on bills or ledger records when blanks are used: Deduct 10 points for each error.

No. 4 Class of Error. Errors in spacing, running bills together on balance sheets, clerical errors of extensions, errors on statements, failure to leave proper spacing to facilitate count of customer: Deduct 5 points for each error.

Work done on Elliott-Fisher and "Ditto" machines to be rated as follows:

Residence billing and all overdue statements run on "Ditto" machines: One point each.

Commercial and disconnect billing, are to be counted as two points for each bill, as this work is very much slower than residence billing: Two points each.

Steam, weekly, special, municipal, sign, creamery, and deferred billing, also typing of merchandise and regular overdue statements are to be counted as three points for each bill or statement. It takes three times as long to bill this special work as residence billing: Three points each.

Primary and Energy Power Billing. Typing of weekly, energy, steam and special municipal overdue statements are to be counted as 5 points each, due to a great share of statements having many balances to be typed on. Five points each.

When the 400- or 900-mark is passed, the even figure of 500- or 1000-step of the rate scale is to be allowed.

Adding the points made on special work to total points made on regular work will increase the production per machine, as it will have a direct bearing on the operator's wage.

The above schedule will eliminate lost time and increase production, efficiency, and accuracy, as the application must be even closer than heretofore.

EXHIBIT VII

ACCOUNTING DEPARTMENT, METER-READING DIVISION

Comparative Report of Costs and Averages

Unit cost	Incentive-wage plan, Dec., 1929	Regular wage plan, Dec., 1922	Per cent or increase of Decrease
Regular readings	0.0234	0.0278	15.8
Skip readings	0.0729	0.0963	24.3
Rereads read	0.0479	0.0852	43.8
Special readings	0.1924	0.2982	35.5
Total readings	0.0277	0.0371	25.3
Bills delivered	0.0080	0.0099	19.2
Averages:			
Regular readings	399	324	23.1
Skip readings	136	99	37.2
Rereads read	194	114	70.1
Special readings	46	43	6.9
Bills delivered	1034	782	32.2
Wage per day per man	$7.04	$5.47	28.8
Employment Bureau record of labor turnover	1%	20%	

The differential is approximately the same for each month.

Included in the above costs are labor, supervision, automobile expense, and all supplies, such as stationery, flashlights, batteries, shoe and shoe repairs.

Meter-Readers' Wage Schedule (Effective June 8, 1923). The following scale of wages will be effective the first Monday in each calendar month, as of the preceding calendar month's record.

No. of Readings per month	No. of skips	No. of rereads	Wage per hour, cents	Average readings per day	Unit cost
6,900	550	69	55	300	0.0173
7,600	600	76	60	330	0.0172
9,000	700	90	65	390	0.0157
9,700	775	97	70	422	0.0157
10,400	825	104	75	452	0.0157
11,500	900	115	80	500	0.0151

Penalties

1 Deduct 10 readings from total for eack skip or reread in excess of number allowed as above.

2 Deduct 50 readings from total for each day's work counted incorrectly.

3 Deduct 50 readings from total for each meter in route not read because of not finding card.

4 Deduct 50 readings from total for miscellaneous errors in each day's work.

Billed for less than 16 days	200
New and turned sheets	200
Omission of stamps	200
Failure to order larger or smaller demands	200
Failure to rule out reading	200

EXHIBIT VIII

In general, because of the switching of employees from one type of work to another, we measure our work in standard minutes or points, which gives us the necessary common denominator.

Our task is expressed in per cent, in order to make comparisons between dissimilar jobs and departments possible. We prefer the per cent method of expression to other methods, such as "point-hour" etc., because it is familiar to all interested people.

Our bonus payment starts at 70 to 75 per cent of task. One hundred per cent is a goal to be attained and slightly exceeded continuously by the average of the group on bonus. We expect the exceptional person to attain 120 to 125 per cent of task.

Our rate of payment is ²/₃ to ³/₄ per cent of a base salary for each 1 per cent improvement (above starting point) on the bonus scale.

BONUS PLAN FOR TYPISTS IN THE CORRESPONDENCE AND MAIL-ORDER DEPARTMENTS OF THE B. OF A.

Approved by B. of O. 11/8/29

The bonus plan which is outlined below (as recommended for adoption by the Operating Department and the Planning Department) was approved by the B. of O. on Nov. 8, 1929.

The plan is to replace the increasing salary scale plan which until recently has been operating in the above departments.

The essential features of the bonus plan are:

A. It will be an individual bonus; i.e., each person's earnings depends upon *her own* rate of production only.

Employees whose symbols are BCT and BMT are regularly included in the plan. Any other typists doing bonus work will be paid a bonus (if earned) for the time spent doing such work.

B. *Bonus Task or 100 Per Cent Efficiency.* An average of 60 points of work produced per hour or 2880 points per full 48-hour week.

C. *Bonus Starting Point or 70 Per Cent Efficiency.* 42 points of work produced per hour or 2016 points per full 48-hour week.

D. *Bonus Payment.* 12 cents for each 25 points produced over the minimum amount required for the week.

Time spent in other sections or divisions on non-bonus work is not included when calculating the required production per week; i.e., if a typist spends 40 hours doing bonus work and 8 hours doing non-bonus work, her required production for that week would be 40 × 42 points per hour = 1680 points of work.

No bonus is paid for time spent on non-bonus work.

E. *Record of Production and Time.* The individual daily card used at present for production and time records will be continued. The following data are recorded on this card:

1 For Bonus Work: Class of work and number of pieces of each class
2 For Non-Bonus Work: Kind of work done and number of pieces if possible
3 Time work was started
4 Time work was finished.

All work is counted and distributed to each typist by a distributing clerk. The distributing clerk records this count on the daily card. Work which is done over because of errors on the part of the typist is not recounted.

The detailed record collected on this card is required for operating purposes within the department and *not for bonus records.*

For bonus purposes the Statistical Division of the B. of A. will summarize this data as follows for each person:

1 Multiply the total number of pieces of each class of work by the point allowance per piece (for that class of work) to get the number of *points* produced for each class. Add all classes to get total point allowance for the day
2 Get total hours spent on bonus work
3 Get total hours spent on non-bonus work.

This summary data will be posted to a weekly individual time and production card by the Statistical Division. These weekly cards will also state the type of work done for which non-bonus time is claimed.

These weekly cards will be forwarded to the Controller's Office for the purpose of calculating the bonus. The original records from which the data was summarized are subject to audit by the Controller's Office at any time.

(NOTE: Non-bonus time includes only such time spent *doing work* for which there is no point allowance, such as work in another department or division. All other allowances are provided for in the Standards—see Planning Department memo dated 10/28/29.)

The following (Paragraphs F, G, H, and J) to be done by the Controller's Office:

F. *Analyze the Weekly, Individual, Time, and Production Cards.* The Controller's Office will total each employee's weekly time card to determine—

1 Total hours on bonus work
2 Total hours on non-bonus work.
(The total of 1 and 2 must be checked with Salary Office and overtime figures.)
3 Total points produced.

G. *Calculate the Bonus.* The following steps are necessary to calculate the bonus each week:

1 Multiply hours on bonus work that week by 42 points per hour to get the minimum number of points required
2 Subtract the minimum points required as found in (1) from the Total Points produced (F-3)
3 Divide the difference by 25 and multiply by 12 cents.

H. *Calculate the Efficiency of Each Person.* The following steps are necessary:

1 Divide the total points produced (obtained in F-3) *by* the total hours on bonus work (F-1) times 60 points per hour.

J. *Present Summary of Data.* The Controller's Office will furnish the following data for the week for each person to the Operating Department (2 copies), the Budgeting Office, and the Planning Department:

1 Total points produced (F-3)
2 Total hours on bonus work (F-1)
3 Minimum required points (G-1)
4 Number of points produced over minimum (G-2)
5 Amount of bonus earned (G-3)
6 Efficiency of each person (H-1)
7 Total hours on non-bonus work (F-2)
8 Nature of non-bonus work done or department or division worked for (from weekly cards).

K. *Schedule of Bonus Payments for Salary Office.* The Con-

troller's Office has given two copies of the summary data (see Par. J)to the Operating Department. One of these copies must be initialed by the department manager and the assistant general manager, and then forwarded to the Salary Office by the Operating Department.

L. *The Operating Department* will present the data supplied by the Controller's Office to the typists included in the bonus.

M. *The Budgeting Office* will determine a weekly unit cost and savings for BMT and BCT employees as follows:

1 Determine total base salary cost for the week, as follows:
   - *a* Get proportion of hours spent on bonus work to hours spent on non-bonus work (F1 and F2)
   - *b* Get total base salary (not including bonus) paid to BMT and BCT symbols (salary comparison sheets)
   - *c* Multiply base salary (*b*) by ratio determined in (*a*)

2 Add total bonus earned for week (total of J-5 above)

3 Divide total salary (base salary plus bonus) for the week by the total points produced for the week (total of J-1 above). This is the unit cost

4 Subtract the unit cost thus obtained from the past unit cost (see next paragraph) and multiply by total points produced for the week (total of J-1 above) to obtain total savings for the week.

N. *Past Unit Cost.* In order to obtain a reliable record of future savings, it is necessary that the past unit cost used as a basis for measuring savings be a definite and unchallenged figure.

It is recommended, therefore, that the individual daily time and production records covering the work of all BMT and BCT employees for the four weeks ending 11/9/29 be analyzed by the B. of A. Statistical Division in the exact and complete manner outlined in this report. The average unit cost thus obtained for the four weeks noted shall be accepted as past unit cost. The Statistical Division shall report this past unit cost to the Budgeting Office.

It shall be understood, however, that this cost will be considerably lower than the former cost would have been since this department has been operating under a type of incentive for a period of about two years. Therefore any future savings must be made over and above a considerable previous improvement.

The various classes of work and the corresponding symbol and point allowance per piece are as follows:

Class of work	Symbol	Time or point allowance per piece
Paid mail register entries	PMR	0.35
Addressing envelopes, typing stubs (M.O.D.)	A	0.37
Enter-ups, C.P.I. record cards, form 2283	EU	0.43
Form letters filled in (one, two, and three words)	FL 1	0.75
Form letters filled in (Controller's Office forms) Copy-offs	FL 2	1.83
Paid mail-order cards	PMO	0.87
Transcripts M.O.D.	T	0.94
Order backs (Elliott-Fisher)	FL 3	1.74
Form letters typed (tallies up to 10 lines, bills up to 10 lines, 2nd complaint transcripts)	FLT 1	2.08
Charge tickets (Royal Manifold) form letters typed, bills over 10 lines and tallies over 10 lines	FLT 2	3.47
Reports Class 3	R 3	0.42 per sq. in.
Reports Class 2	R 2	0.47
Reports Class 1	R 1	0.58

The Clerical Costs involved are:

B. of A.—Same as at present.

Controller's Office—Same as for the packers' bonus recently approved. This was estimated by the Controller's Office as a maximum of two days, representing a clerical cost of $6.

The bonus rate provides for a split of labor savings (above bonus starting point) of approximately 50 per cent to the organization and 50 per cent to the employee. In this respect it follows the basic plan used for the recently approved packing unit and the accounts payable bonuses.

It is management's function to see that any person who is hired at a higher-range salary reaches the minimum production and approaches the task in a reasonable length of time.

Special Penalties: 1 All incorrect work must be done over and is not recounted.

2 For 10 errors per week, no additional penalty.

3 For every error over 10, one unit of work will be subtracted from total production (this applies to both kinds of work).

Equipment: Comtometer and Mercedes machines.

Duties: Comptometer Operations:

(*a*) Calculate *cost* and *selling* totals on invoices, shorts, overs, returns, markdowns (etc.), mdse. transfers, mfg. dept. sales, special purchases, journal transfers, and charges. (Charges are made out by the comptometer operators)

(*b*) Add discounts on individual vouchers and obtain total discount on all vouchers for comparison with bookkeepers' total. It is estimated that this work takes approximately 15 min. per day for each first figurer. Each first figurer is given approximately an equal number of vouchers to do. These are not counted in the person's production, an allowance having been made for this work when setting up the production standards.

Mercedes Operations:

Calculate *discount*, amount of anticipation, and per cent mark-on for items listed in (*a*)

Units Counted: All items listed in (*a*) above are counted in three separate groups as follows:

(*a*) Invoices
(*b*) Charges[1]
(*c*) Other items (shorts, overs, returns, markdowns (etc.), merchandise transfers, mfg. dept. sales, special purchases, and journal transfers).

Only 1/2 unit is allowed for each charge as this involves only one-half as much work as in the case of other units.

Where Count Obtained: Each person counts her own production. Total of all persons can be checked with total of all second figurers.

Past Records: Average production (7th through 17th wk. Spring, 1929).

	Comptometer	Mercedes
Units per day	402	637
Maximum production, single day	729	2130

Past *actual* salary range, $18 to $25

Past average salary, $22.60

Maximum salaries paid during period Feb. to Oct., 1929:

1 person	$27
1 person	$29

Cost per 100 units, Spring, 1929, $1.531

$$\left[\begin{array}{l} 1 \text{ day} \div \frac{402}{637} \text{ days} = 1.631 \text{ days for 402 pieces} \\ \$22.60 \div 6 \text{ (days)} \times 1.631 \text{ (days)} \div 4.02 \text{ pcs.} = \$1.531 \text{ per 100 pcs.} \end{array}\right]$$

Special Penalties: Deduct 20 units for every error during week. (This is approximately 5 cents per error.)

Equipment: Comptometer (also 1 Electric Burroughs on trial).

Duties: Refigure all work calculated by 1st figurers except percentage work on which is to be checked by inspection and refigured if it looks wrong. All errors found are to be noted and the items returned to the first figurer for correction.

Units Counted: Same items counted by first figurers but divided into four groups as follows:

a Invoices
b Charges (full credit given)
c Markdowns, etc.
d Other items (shorts, overs, returns, mds. transfers, mfg. dept. sales, special purchases, and journal transfers).

Where Count Obtained: Each person makes own count. Total for all second figurers can be checked with first figurer's count.

CONTROLLER'S OFFICE—ACCOUNTS PAYABLE BONUS

Name of Job: Control Typists — No. of People 2

Efficiency		Production Units per day	Production Units per week	Earnings: Salary range	Earnings: Assumed average salary	Earnings: Bonus earned	Unit cost: Cost per 100 units at average salary, Spring, 1929	Unit cost: Cost per 100 units at average salary, October, 1929
Par	125%	1600	....	.....	....	....	....	....
Task	100%	1280	7680	21.34– 24.34	$23.34	$3.34	$0.304	....
Starting pt.	75%	960	5760	18.00– 21.00	20.00	0.00	0.347	....

Equipment: Remington-Wahl bookkeeping machine.

Duties: Types debit and credit invoice register sheets by ledger, subdivided by debits and credits and further subdivided into 5 departmental groups. Obtains subtotal for departmental groups and the grand total for all departments in the ledger. Items typed are invoices, shorts, overs, returns, transportation ticket (where vendor pays), and charges.

Units Counted: Invoices (including special pay invoices which have already been paid) shorts, overs and returns, transportation tickets (where vendor pays) and charges.

Where Count Obtained: From typewritten (invoice register sheets) person makes own count.

Past Records: Average production (7th through 17th wk., Spring, 1929).

Units per day	985
Maximum production, single day	1609
Average salary above 11 weeks	$24.50
Actual salary range, Feb. to Oct., 1929	$20–$25
Present average salary (10–15–19)	$23
Present salaries (10–15–29)	$22 and $24
Cost per 100 units, Spring, 1929	$0.424

NOTE: *Re* penalties: This person's errors would delay the voucher clerk when proving figures. Therefore voucher clerk will bring more pressure to bear on control typist than any arbitrary penalty would be able to do.

CONTROLLER'S OFFICE—ACCOUNTS PAYABLE BONUS

Name of Job: Voucher Clerks — No. of People 5

Efficiency		Production Units per day	Production Units per week	Earnings: Salary range	Earnings: Assumed average salary	Earnings: Bonus earned	Unit cost: Cost per 100 units at average salary, Spring, 1929	Unit cost: Cost per 100 units at average salary, October, 1929
Par	125%	675	....	.....	....	....	....	....
Task	100%	540	3240	$26–$29	28.00	$4.00	$0.864	....
Starting pt.	75%	405	2430	22– 25	24.00	0.00	0.988	....

Equipment: Remington-Wahl bookkeeping machine.

Duties: Sorts invoices, etc., by vendor, types voucher for each vendor, and types name and address on check portion of voucher.

Units Counted: The unit is the number of entries on all vouchers (not number of vouchers). Therefore the units counted are all invoices, shorts, overs, returns, transportation tickets (where vendor pays) and charges.

Where Count Obtained: Each voucher clerk counts her own production. The total must equal the control typists' total less the special pay invoices (already paid).

Past Records: Average production (7th through 17th wk., Spring, 1929).

Units per day	399
(Average of 399 = 366, 384, 388, 420, and 438 for five individuals)	
Maximum production, single day	762
2nd highest production, single day	669
Average salary, above 11 weeks	$24.60
(Salaries = $21, $24, $24, $24, and $24)	
Maximum salary during period Feb. to Oct., 1929	$26
Cost per 100 units, spring 1929	$1.03

NOTE: *Re* penalties: Voucher clerk must prove her own figures. If incorrect, must find error on own time. No additional penalty necessary.

Equipment: Remington-Wahl bookkeeping machine.

Duties: Enters debits and credits on vendor's account. Sets up cash and discount figures.

Units Counted: All invoices, shorts, overs, returns, transportation tickets (where vendor pays) and charges plus special pay invoices (already paid) plus number of vouchers (for cash entries).

Where Count Obtained: Each bookkeeper counts her own production. Checked with voucher clerk's records and check register's records.

Past Records: Average production (7th through 17th wk., Spring, 1929).

Units per day	612
Max. production, single day	1064
Average salary—above 11-week period	$26.60
Actual present salary range	$25–$29
Maximum salary, Feb. to Oct., 1929	$29
Cost per 100 units, Spring, 1929	$0.724

Spring, 1929—7th through 17 weeks

Average prod.	Sal. paid
552	$20
570	26
573	25
660	26
705	27

Equipment: Defiance check writer.

Duties: Record amount of money on checks (embossed).

Units Counted: All regular vouchers listed on check register sheet plus special pay vouchers (to be paid) received from special pay clerk.

Where Count Obtained: Total of check-register typists plus total from special pay clerk's check register sheet.

Past Records: Average production (7th through 17th wk., Spring, 1929).

Unit per day	934
Maximum production, single day	1609
Time-studied production (Using average times + 10% fatigue and 395 min. working time)	1790
Average salary during above 11-wk. period	$20
Present salary	$20
Maximum salary, Feb. to Oct., 1929	$22
Cost per 100 units, Spring, 1929	$0.356

EXTRACT FROM BONUS PLAN FOR ACCOUNTS PAYABLE DIVISION OF CONTROLLER'S OFFICE

B *Production:* Production will be counted in units for each job but translated into "points" in order to provide a uniform measuring stick for different kinds of work.

A point equals the amount of work which should be performed in one minute when performed at a rate of speed which we consider to represent 100 per cent efficiency.

C *Bonus Task or 100 Per Cent Efficiency:* The bonus task equals 60 points produced for each hour worked and is considered to reach and exceed. We expect the average production on every job to be at least 100% or better after a reasonable period of time.

D *Bonus Starting Point or 75 Per Cent Efficiency:* In order to encourage employees to reach and exceed 100 per cent efficiency (they now average around 75 per cent), we shall start paying a bonus whenever a person's production exceeds a minimum efficiency of 75 per cent. To be 75 per cent efficient, a person must produce 45 points of work for every hour she works (on bonus work). This is the minimum requirement.

E *Bonus Payment:* This will equal a certain amount for every 100 points produced over the minimum requirement. The amount will vary with each job and will be high for higher-salaried jobs.

MAN-52-10

Management of a Large Plant: How to Retain the Advantages of the Small Plant

By A. B. REYNDERS,[1] SPRINGFIELD, MASS.

Experience shows that one man cannot efficiently supervise more than ten others. Each assistant should have definite duties and responsibilities in order to become a regular superintendent or foreman. A carefully planned organization with clearly defined duties for each position will accomplish much, but the selection of proper men is of great importance. The success of a small concern depends almost entirely upon its personnel. As the organization grows its functioning consumes more time, and a large corporation must function through written instructions. A large plant has the advantage of quantity production and can also obtain the advantages of the small plant by careful attention to details. The advantages usually considered as resulting from a small plant are quick action, low-production cost of small quantities, and close relationship of employee and employer. The paper discusses each of these advantages and outlines methods of obtaining them in large organizations.

THE sole object of any manufacturing plant is to make money by rendering a legitimate service. Some may think that they are in business to maintain a reputation, to produce wonderful engineering feats, to give employment to a small or a large number of employees, but in the final analysis, unless they are operating a charitable or a governmental institution, they must make a monetary return on the invested capital or else, ultimately, cease to do business. Whether a large or a small concern, this is true. How it is accomplished varies. In a small company, this responsibility is directly assumed by the owners. In a large concern, the owners, commonly called stockholders, are many, and the responsibility for results is delegated to an employed organization. The control or direction of this organization to obtain the desired results is known as management.

The form of an organization is of vital importance to its functioning. If it is not set up properly, the management will be inefficient. The larger the organization, the more necessary it is that all activities be covered and that the duties and responsibility of each individual in charge be definitely fixed. Overlapping of duties causes confusion, with resultant loss of time and costly errors.

A large manufacturing enterprise would do well to pattern its form of organization somewhat after the oldest organization in the world, the army. It has its line for fighting, its staff for advice and coordination, and its councils for specific tasks. Long experience has shown that one man can, with efficiency, personally supervise the efforts of not more than ten men.

In a large industrial corporation, the owners or stockholders elect a board of directors, the board of directors elects the officers, and the officers, in turn, appoint the managers, the supervisors, and so on down the line. Graphically, this may be described as an hourglass type of organization, starting with a large number of owners, concentrating in a chairman of the board or a president, and then expanding to cover various activities. In general, these activities are centered about three major divisions, selling, designing, and manufacturing. In addition, there are various allied activities such as the financial department, the legal department, the accounting department, the credit department, etc. This constitutes the line. Certain officers of the corporation, such as the vice-president in charge of manufacturing, require a staff of experts to advise the managers of the different plants or to coordinate their efforts. In addition, various committees are formed from time to time to perform certain functions, such as welfare committees, safety committees, etc.

Just as in the army, such an organization will be found to function best when one officer or supervisor personally directs not more than ten men. Here the author wishes to make a statement which has been the result of some years of observation. Every assistant should have definite duties and responsibilities. If he has duties assigned to him from time to time by his immediate superior, he either becomes a glorified secretary or else he assumes authority and runs the job. In both cases, he is a misfit. An assistant with definite duties becomes a regular executive, such as a superintendent or a general foreman. A carefully planned organization with clearly defined duties for each position will accomplish much, but the selection of the proper men is of the greatest importance. In fact, the success of a small concern depends almost entirely upon its personnel. Many a poor organization functions because of the high-grade men directing it.

From now on, the remarks will be confined to certain features of factory management only, with no attempt to cover all activities of the corporation. Such activities as executive control, sales, engineering, legal, research, etc., will be mentioned only briefly in relation to the works. However, before proceeding on factory management, it would be well to define what is meant by a *large* plant and what is meant by a *small* plant. Such terms as "large" and "small" are relative. For the purpose of this paper the number employed will be used as a basis for classifying a plant as large or small; a large plant having 1000 or more employees; less than 1000 employees being considered small. Also, to be concrete, the plant to be discussed will be considered as one manufacturing electrical apparatus, both in large and small quantities, and having as a maximum number of employees around 5000.

As soon as an organization grows in size, it begins to consume time in its functioning. This time-consuming propensity is the greatest objection to increasing the size of a plant. It is obvious that, when so many persons are employed, oral instructions cannot be followed without involving too great a hazard in execution. A large corporation is therefore compelled to function through written instructions. The customer's wants are usually determined and set down in "black and white," the engineers use these requirements as a basis for their drawings and specifications, and the factory works to the drawings and specifications in executing the work. The larger the company, the less value any oral instructions have. The result of this method of doing business is a definite understanding by the customer on what

[1] Works Manager, Westinghouse Elec. and Mfg. Co.

Contributed by the Management Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

he is to be given and an equally definite understanding by the manufacturer on what he is to furnish, but it has the disadvantage that it takes time. Not only is time lost, but expense is incurred for stationery, for typing, for transmitting from place to place, for recording, for filing, etc. This increases the overhead, the greatest bugbear of modern business management. Again, the executives in charge, being unable personally to handle the details, must depend on reports and records to reach decisions or to issue instructions. Additional paper work and more time are thus required, and up goes the overhead again. A small plant possesses a decided advantage in this respect. Now let a typical factory organization be taken and show how it functions.

Cost Accounting

As stated previously, the sole object of any manufacturing plant is to make money. To do this, it is essential that factory costs be known immediately after the apparatus is delivered. If this does not occur, estimates on new business are likely to be wild guesses. Factory costs are usually compiled by adding the cost of the material, labor, and overhead. Deviations from the allowed time and estimated materials which actually occur are treated as variances, and such variances are absorbed each month through the profit and loss accounts. Material costs are compiled from the drawings or the specifications, labor is obtained from the time cards of the workmen, and the overhead includes all expense, both labor and material, that cannot properly be charged direct to the order. It is the object of good management to reduce this item to a minimum, although it does not necessarily follow that low overhead means low cost. Usually the installation of labor-saving machines means an increase in overhead, but a decrease in the total cost. Sometimes labor and overhead are combined in one figure, and then designated as the department rate. This rate, multiplied by the "time taken," and the product added to the cost of the material, gives the factory cost under what is known as the standard cost system.

On the assumption that the designs as furnished by the engineering department are settled, it becomes the duty of the factory organization to keep the cost to a minimum by:

1 Purchasing material at the lowest market price to obtain the desired quality
2 Time study to reduce direct labor to a minimum
3 Budgeting to keep the overhead within definite limits.

It is the duty of the accounting department to maintain records of the results accomplished along these lines and to make concise but comprehensive reports so that the departmental heads can plan for corrections or improvements.

This department furnishes to the interested departmental heads a factory expense report. This form shows all the expense items, such as salaries and wages for foremen, for rate setters, for inspectors, defective work, depreciation, maintenance, etc., and the allowance for each item for the week, the month, and for the financial period, etc. Opposite each allowance is placed the actual expenditures or the amount spent in excess of the allowance. Such allowances are of little value unless they are rigidly adhered to. The original method of enforcing them was to permit no raises in salaries unless the budget figures were met. Later on, a bonus was offered if the budget figures were lowered.

Cost Reduction

It should be understood that a cost-accounting department is a recording department; that it does not reduce the cost, only calls attention to the facts as they have occurred. It is essential in this day of keen competition that aggressive cost reductions be constantly carried on. While this should be done by the designing engineers and by the operating forces in the factory, it is not their prime function. It has been found that a separate department, manned by men of technical training, with years of shop experience, has solved the problem. This department is called the cost-reduction department. Having in this department a group of selected men whose sole duty is to check into all quantity production for the purpose of saving pennies cannot be too strongly recommended. Being free from all routine work, they can concentrate on the study of the designs, processes, tool equipment, machine tools, floor arrangements, or any other factor entering into the cost Their recommendations for expenditures must always be accompanied by a statement of the savings. Usually, if the cost can be recovered by the savings in a year, the recommendations are adopted. At the end of the year, the accounting department sends to the works manager a report showing whether or not the savings have been made. The author could, if time permitted, tell of some almost unbelievable savings that have been accomplished by this department on such standard lines of product as washing-machine motors and fan motors. Their efforts are not usually directed to special products, because such designs are not repeated often enough to warrant the expense. The designing engineers and the regular works organization are expected to take care of the cost of these products.

Time-Study Departments

In all modern large plants some form of incentive wage-payment plan exists. Whether this be piece work, standard time, or any one of the many combinations, it is based upon a time study of some sort. It is obvious that this time study must be made by a disinterested party having the necessary shop experience to distinguish between false moves and necessary ones, to detect lost motion and improper handling, to decide whether the machine tools are suitable, the small-tool equipment ample and of the right sort, etc. The men assigned to this task form what is often called a time-study or rate department. The tendency is to set the time for performing each operation before the job is placed in work, especially when the operations are similar to previously performed ones. When they are radically different, a time study with a stop watch is usually made on the first production under day work.

Piece work is rapidly being superseded by other forms of incentive wage payments on account of its inflexibility. The official wage-payment system of the Westinghouse Company is known as "standard time." Under this system, every operation is timed so that it can be performed in that time by the average worker. If more time is taken, the operator gets the guaranteed day rate; if less, he obtains the allowed time at his hourly rate and a bonus. This system permits paying the going hourly rates, thus allowing costs to fluctuate with general market conditions.

As labor is one of the most important items in the cost, its conservation must be watched by the management. For this purpose, regular reports are prepared by the accounting department and distributed to interested departmental heads.

Purchasing

Material is the largest single item entering into the cost of the product. It is therefore essential that it be purchased at the lowest price to secure the desired quality and delivery on time. Even in a small concern, purchasing becomes a specialty. In a large concern, it becomes an organized specialty. Contact must be made with competitive suppliers, specifications for quality, etc., must be transmitted, terms of payment settled, delivery dates specified, etc. In large corporations doing business with a multitude of customers, reciprocal buying cannot be overlooked. The purchasing department under the direction of a purchasing agent performs these functions. How well this is done is judged by reports furnished to the executives in charge. One deviation

from standard practice has been found to be of value. While the purchasing department specifies the date of delivery on the purchase order, the following of this date to see that it is met or the changing of the date to meet a changed condition in the factory is the function of the scheduling or production department. In other words, the purchasing department makes the contracts, and another department deals direct with the supplier on delivery. This has worked very successfully, as quick action can be secured by the department most interested.

Scheduling

It is essential in a large plant that a systematic method be followed in furnishing delivery dates to customers, and then that these dates be followed to see that they are met. This is the function of the production, scheduling, or planning department. Quantity apparatus produced for stock is generally scheduled for a certain amount per month. Each day's production is recorded against this monthly bogey. Graphical charts, if simple, are an excellent means for following this type of production.

Special apparatus has to be handled as individual items. Each date has to be followed by some sort of a tickler file. For the management to judge whether or not this special apparatus is being delivered on time before complaints are received from the customer, a record is furnished showing the percentage of overdue orders in relation to the orders due during the month. A careful following of this record eliminates many embarrassing situations.

In addition to scheduling deliveries and constantly checking them, this department is responsible for ordering the material from the drawings and specifications and checking to see that it is delivered on time. The stores and stocks naturally come under the jurisdiction of this same department, likewise the packing and shipping.

Selection of Machine Tools and Small Tools, Factory Layouts

In a large manufacturing concern, the selection of the proper tools to perform the work in hand is most important, as large sums of money are involved in the purchase of the tools, and the time required to perform operations is definitely settled by the type of tools selected. The problem of reducing costs of certain designs without reducing wages is solved by reducing the labor required per piece. To accomplish this, labor-saving machines and small tools such as dies, jigs, and fixtures must be provided. When there is sufficient quantity, the purchase of such machine tools and small tools is easily justified. In many cases the desired machine tools do not exist on the market, and therefore have to be designed and built in the plant. A large tool room, therefore, becomes a necessary part of a large plant. The cost for operating such a tool room is quite an item, and as it is included in the overhead, the most efficient equipment and personnel should be provided.

After the necessary machine tools and equipment have been selected, the proper arrangement or grouping of these tools in the allotted space must be made. To reduce the cost of handling material, the accumulation of excess parts, and damage while in transit, conveyors of various kinds are used or else benches and machine tools are so grouped that the work can be passed along by the operators. Conveyors, particularly of the continuous-traveling overhead type, are fast gaining in favor, as they eliminate all tote pans, trucks, or other containers, and there is no need to pile the material in storeroom bins, only to be unpiled and removed later on. These "traveling storerooms" also furnish quickly an indication of too much or of too little stock. All factory layouts should be made in the form of tracings after the approvals of the departmental heads in charge of the operations have been obtained. From time to time, changes in the arrangement have to be made to secure the greatest economy. Such changes should always be incorporated on the tracing.

Inspection and Test

Nothing is so vital to maintain quality as inspection and testing. Without an adequately equipped and manned inspection department and test department, it would be practically impossible to operate any incentive wage-payment plan. It is obvious that those in charge of production are inclined to say that their product is good enough to ship. In a small plant, where the superintendent or foremen are familiar with the economies of the business and the consequence of sending poor work into the field, it is possible, and often practical, for such men to pass upon the quality. In a large company, the inspection and test departments are entirely independent from the manufacturing organization, the chief inspector reporting direct to the works manager. While this independence exists, it is essential that the inspectors work closely with the foremen and exercise good judgment in passing upon questions which may be matters of opinion, such as appearance and noise.

The amount of inspection in a plant is always subject to criticism as it is one of the large items entering into the overhead. It varies considerably with kind of apparatus manufactured, whether it is special, whether it is repetition production, etc. When the group system is used, it is greatly reduced, as inspection of the finished product only is required. A record of all rejects must be maintained and be given regular and careful attention. Too great a percentage merits penalization, particularly if repeated frequently by the same individual.

Plant Maintenance

In a large plant the maintenance of the buildings and building equipment, the grounds, roadways, pipe, and power lines is carried on in a systematic manner by a separately organized department. Nothing promotes a finer "esprit du corps" than to have all the buildings and equipment in first-class repair, the floors clean, windows washed, ceilings and walls painted, and an air of orderliness throughout the department. The toilets, wash rooms, and drinking fountains should be kept scrupulously clean. Plenty of spittoons should be provided, otherwise the cutting compound in machine tools may be contaminated with tobacco juice. Corners of stairways should be painted white, with the word "Don't" added in large black lettering.

Safety Work

In a well-managed plant, safety has a very vital place. From a cold-blooded standpoint, accidents are costly, and whether the company carries its own insurance or has it carried by a stock insurance company, it pays the bill. It is comparatively easy and is now quite general practice to guard the hazardous parts of machine tools. It is more difficult to get operators to follow instructions, such as wearing goggles, safety shoes, operating the safety devices, etc. Most accidents are due to this cause.

Physical examination now so prevalent in large plants has a beneficial effect in reducing accidents. By this means, employees are being assigned tasks suited to their physical condition and are fast learning the value of keeping the body in condition.

If some of the foolish laws on liability, such as the manufacturer being responsible for the loss of both eyes if he hires a one-eyed man, are modified, industry will readily employ more of the partially disabled, and by means of this physical examination, place them on suitable work.

Safety from fire is particularly well taken care of in a large plant, principally because of the rigid inspection and reasonable requests from the insurance companies for the installation of

safety appliances, such as sprinklers, fire walls and doors, fire extinguishers, etc. In safety work, prevention is far cheaper than the cure.

How to Retain the Advantages of the Small Plant

The advantages that a small plant possesses over a large plant are:

1 Ability to act quickly
2 Low cost on production of small quantity orders or special apparatus
3 Close relationship between employee and employer, tending toward a better understanding of mutual problems.

With the advantage of quantity production being in favor of the large plant, how can one at the same time obtain the aforementioned advantages of the small plant? This has been accomplished to a large extent in a number of concerns.

Ability to Act Quickly

In the Westinghouse company there always has been an adverse criticism on the quickness with which delivery could be made on special apparatus. It has been found necessary frequently to accept orders for special motors involving a change in windings or a different shaft length or mounting, on account of having quantity business of standard lines. It has been the practice to produce these so-called "specials," usually in small quantities, in the same department where the larger quantity apparatus was being produced. The result has been that the special apparatus is pushed aside by the workman because he cannot earn as much in producing it, by the foreman because of the difficulties in adjusting the equipment and selecting the operators, by the production clerks on account of the large amount of paper work involved, and so on up the line. After struggling for some years with the problem of producing these small quantity "specials" in as short a time as the small manufacturer, it was decided to organize a separate department for the production of orders of 10 units or less, regardless of whether those units were standard or special. If they were standard, parts were requisitioned from the department manufacturing the quantity, and only the special features or special assembly performed in the small-order department. All-around mechanics were employed. Universal types of tools, instead of special tools, were installed. In order to obtain the greatest effort on the part of the supervisory force to deliver the finished product on time, a bonus was offered, based on the overdue percentage at the end of the month. The result of the operation of a department of this nature has reduced delayed shipping dates to a negligible percentage. Instead of avoiding small orders, the company is now in a position to solicit this kind of business.

One other very important object was attained—namely, the ability to determine the actual cost of these special units—whereas before they were merged with the cost of the standard product to the detriment of the standard apparatus. This idea of separating the small-quantity special apparatus from the larger quantity apparatus has been followed for some time in the production of other lines, such as repair and spare parts. In the latter case, a separate factory has been established at Homewood, Pa., solely to produce non-current parts.

Low Cost on Small-Quantity Production

In a large organization, this is a difficult object to accomplish, due principally to the large overhead. It can be accomplished only by adopting the same practice as is followed in the small shop. In other words, the large plant must be departmentalized and equipped to carry out the same functions as a small plant. The aforementioned small-order department accomplishes this to a great extent, as experience proves that when the execution of an order drags out, the cost increases, and nearly always exceeds the estimate.

Contact Between Employee and Employer

It is impossible in a large plant for the president, or even the works manager, to know personally all or even a majority of the workers. That intimate personal contact between the "boss" and the man on the drill press can never be depended upon in a large organization to secure results. Something must take its place. Hence, an incentive plan for the worker permitting him to earn in proportion to his output. There are various schemes of paying in proportion to the output, ranging between day work and straight piece work. Only a few plants operate entirely on the day-work plan, and even in those plants the operators who fail to keep up to a standard are generally replaced.

An equal amount of effort on the part of the management has not been used in providing an incentive to the supervisory force. Of late, however, in many plants this has been recognized, and a supervisory bonus has been installed. This bonus is usually based upon a saving of expense or a saving in the direct labor in the product. It is obvious that some standard must be set up as a basis for this saving. While it has been argued that expense should be kept in proportion to the productive labor, a little reflection will disclose that it is an impossibility to obtain; therefore a bonus based on savings made in direct proportion to the productive labor is impossible to obtain when productive labor falls below normal, and is easy to obtain when productive labor goes above normal. The answer is to measure the expense on the basis of a curve rather than a straight line. This is logical. Why should the supervisory force be cut in half if productive labor is cut in half? One would not think of selling half of the machinery or tearing down half of the buildings to reduce the depreciation account by one-half. It is therefore logical to retain more than one-half of the supervisory force when productive labor drops to one-half. On the other hand, it is not necessary to increase the expense by one-half should productive labor increase one-half over normal. A bonus system has been devised based on a curve, and whether business is good or bad it is possible for the supervisory force to earn an extra amount if they save in expense over the allowed amount as shown by a curve for the different loads. This has had a tremendous effect in reducing costs, principally through overhead. Direct savings in cost can also be made if a foreman or other supervisor devises a new tool or a new grouping of tools which reduces the productive labor; he is entitled to a portion of the saving over a period of time. All of this means that an incentive system for both worker and supervisor acts as a substitute for the one-time personal contact between master and workman.

As it has just been said that the relationship between master and workman has been replaced by a bonus system to secure low cost, so it has been found necessary to replace the same contact with secured interest and pride of workmanship by other agencies. A man on the bench always appreciates an interest displayed by the man higher up in his personal affairs. This applies particularly to his private affairs, his health, the health of his family, the progress his children are making in school, etc. In a large plant, this interest on the part of the men higher up is lacking. It must be replaced, and, again, the organization does the replacing. The welfare department has been modified considerably since the paternalistic days following the war. The conclusion has been reached that welfare work should take care of the important issues of life, employment, sickness, accident, old age, and death, also insurance for the survivors. Some of these, such as accident compensation, industry has had to undertake,

due to legal requirements of the state in which the industry is located. Unemployment is still unsolved, although large industries are more apt to furnish all-year-around employment than are the smaller concerns.

The age limit has received considerable publicity, but in the actual operation of a large plant a man is rarely let go because of age. It is true that he may, due to physical infirmities, be unable to carry on his old work, but usually some lighter work is found, even though the pay may be reduced. Ultimately, he is retired or pensioned. In this respect the larger industry is more humane than the smaller one which does not have the necessary financial resources.

Employees' committees or factory committees composed of representatives of the employers and the employees to look after the welfare of the employees have also received much publicity. In a plant of 5000 or less employees, such committees are not necessary. Too frequently they are not in possession of all facts connected with shop problems, and they develop into fault-finding groups, become involved in wage controversies, and attempt to justify their existence to their fellow workmen by spectacular action rather than by real worth-while work. The functions they are supposed to perform can easily be handled by the foremen, with the understanding that the workman having a grievance can always appeal to a higher authority. In a plant of 10,000 or more employees, such a committee can perform a real function, if carefully selected, as the management is further separated from the men.

Summary

Large-plant management consists in controlling the personnel by arranging them in groups or departments, each to perform a specific duty under the supervision of a specialist. The combined efforts should result in a low-cost, high-quality product. The number of departments must be sufficient to cover all the activities involved in the production of the apparatus from the time an order is negotiated until the apparatus is shipped. The duties of each individual, group, or department should be defined clearly so as to prevent overlapping with resulting confusion. On an average one department head or group leader should supervise not more than ten men.

To be sure that each department performs its functions, a loading or bogey, or a budget, must be set, and thereafter regular reports in concise form of the actual accomplishment must be made as soon as possible after the accomplishment.

Cost keeping and cost reduction are of paramount importance in any size plant. To accomplish this, an incentive system for paying both worker and supervisor is an economic necessity. Expense control must be on a curve basis rather than a straight line.

A cost-reduction department, composed of a group of technical men with years of shop experience whose sole duty is to study designs, processes, tools, and layouts, to save pennies, is almost a necessity in a large manufacturing plant engaged in producing highly competitive products.

It is conceded that the large plant, with its highly organized departments functioning through written instructions, is slower to act than the small plant, with its small organization. This slowness can be partially counteracted by special departments within the larger organization, patterned after the small organization. Such departments should be self-contained in personnel and equipment, and as free from regular system as possible.

Low costs on special and small-quantity apparatus which are secured by the small manufacturer can be obtained by the large manufacturer by also organizing special self-contained departments, patterned after the small plant.

The personal contact between the management and the worker which is very close in the small plant is replaced in the large plant by a welfare department, which looks after the major issues in the life of the worker; namely, employment, sickness accident, old age, death, and insurance for survivors.

Discussion

W. J. Barrett.[2] A shoe-manufacturing company typifies a combination of the large operation through the small plant. This company has decided that a plant capable of manufacturing 300 dozen pairs of shoes per day is the economical size. This size of plant employs approximately 300 workers. In its expansion the company has maintained this size of plant. It now has six units located in the same community, and each unit is capable of turning out approximately 300 dozen pairs of shoes a day.

The company maintains that under this arrangement the cost of supervision is at a minimum, the overhead incidental to record keeping is lower, and operations are on a much more flexible basis.

Allan H. Mogensen.[3] It is interesting to note that the author mentions profits. Mr. Reynders says, "The sole object of any manufacturing plant is to make money by rendering a legitimate service." This question of profit control is one of extreme importance, whether it is a large concern or a small one. And, unfortunately, it is the large plant that usually knows its costs and practices profit engineering. Success in the long run will depend on the ability of the management to so budget their operations that profits are assured regardless of their sales volume. Those concerns that are weathering the present depression are the ones that have charted their course and are steering to it; in other words, they are living within their income.

Depreciation and obsolescence have been mentioned. The writer does not wish to get into a detailed discussion of the various forms of depreciation, but he does want to emphasize one thing. As long as we continue to consider depreciation as a liability, and enter it in the annual statement under that heading, we will find outselves in a difficult situation. Simple as it may seem, the basic rule set down by Dean Kimball, "No profits should be declared until all losses to capital through the revenue account have been replaced from revenue," is often ignored. The depreciation reserve should actually be a reserve, and should be represented by money in the bank or in some form of securities so that the cash will be available when needed. Until this is done, we can talk ourselves blue in the face about replacing worn-out equipment, modernizing the plant, and all the rest. If the money which should have been set aside to do this has been paid out in dividends, a time like the present, when we should be preparing for future production, catches us unprepared.

H. L. Freeman.[4] The paper is correct in its comprehensive outline of departments considered necessary for the management of present-day manufacturing plants, but when the author advocates patterning an organization after the army the analogy is too general.

Taking the branch of service most applicable, the Engineers, there is a combat regiment (849), general service regiment (1179), separate battalion (1071), and smaller special units for pontoon bridges, railway work, camouflage, etc. Instead of ten men, as

---

[3] Assistant Editor, *Factory and Industrial Management*, New York, N. Y. Jun. A.S.M.E.

[4] Cost Engineer, Dixie Construction Company, Birmingham, Ala. Mem. A.S.M.E.

stressed so often in this paper under one man's personal supervision, there is a squad of eight men under the leadership of a corporal who is a working member.

The basic working unit consists of the four-squad operating section under an experienced sergeant. Then there is reached the beginning of the supervision stage, with a platoon of two or more section in command of a second lieutenant, on through a company batallion, to the regiment, the commander of which, a colonel, corresponds to the highest official in a plant employing 1000 men, which has been taken as the dividing line between small and large plants.

The engineer regiment can assign its proper units corresponding with the work required and therefore handle jobs of varying size within its present organization. Unlike the method proposed of having a separate department for special or small-order work, the regular force in a plant could be organized into squads to handle such emergencies and then revert to standard production.

HAROLD V. COES.[5] There is one factor in the management and administration of both large and small plants that is common to both, namely, obsolescence, which is one of the factors of depreciation. In many cases deterioration, the other factor of depreciation, is taken into account and charged into the cost of sales, but very rarely is this true of obsolescence.

There is an economic principle which states that the selling price tends to approach the cost of production, but it should be noted that in this case the economist did not mean cost of manufacture alone or cost of sales alone; the cost of sales included a reasonable profit. The cost of sales should include all the elements of cost. Now it is quite apparent from an analysis, in many cases, that the average return on net worth does not include a sufficient profit to provide an adequate return on the invested capital plus a surplus for future development of the business and to permit the necessary progress of the business by making funds available to care for obsolescence as and when it occurs.

In some instances obsolescence trends can be somewhat forecast. In most cases, however, the developments are so rapid invention follows invention, discovery follows on the heels of scientific discovery, that obsolescence occurs almost like a fire, instantaneously.

The consumer, therefore, is not paying in the price of the merchandise; he is purchasing an adequate amount which will permit the producer to make the progress that the consumers or the public expect him to make by providing surplus earnings over adequate return on invested capital that will permit obsolescence to be cared for, as and when it arises. In many cases the prices are so low that even the element of deterioration is not provided for or is inadequately provided for. Therefore management and consumers alike must learn that obsolescence is a factor to be reckoned with; that it has a definite bearing on profits and a definite bearing on wage earners, and also on continued and sustained prosperity.

AUTHOR'S CLOSURE

Mr. Barrett mentions that a shoe-manufacturing company has decided that a plant employing 300 workers and capable of manufacturing 300 dozen pairs of shoes per day is the economical size.

While this may be true for the shoe industry, the author does not see how so small a plant can afford to have a maintenance department for the upkeep of buildings and grounds and equipment, an accounting department, a purchasing department, and a shipping department. It is true that one of these departments may handle the functions of the other departments and thus reduce the personnel. On the other hand, if a larger unit, say of three or four of these plants, were possible, then the plant purchasing, accounting, shipping, etc., could function economically. At the same time, the factory could be divided into sections, so that each section could produce the 300 dozen pairs of shoes considered to be the economical unit.

Mr. Mogensen stresses the absolute need for setting aside a reserve for depreciation, and that this setting aside should be actual, not theoretical. In other words, the depreciation fund should be available at all times for the purchase of new, up-to-date equipment. The author agrees thoroughly with Mr. Mogensen in his views. Under no circumstances should the fund be used as a means for paying dividends, if such dividends are not available from other sources.

Mr. Freeman takes exception to a manufacturing organization being patterned after the army, as advocated in the paper. He states that instead of ten men, as advocated, eight is the maximum number in the army under the supervision of one man.

In the paper, the number of men under the supervision of one man is recommended to be ten or less, and therefore corresponds with Mr. Freeman's views.

Mr. Freeman also takes exception to the recommendation for a separate department for special or small-order work, and cites the plan used by the army of assigning units to the work required.

This can be done as long as the units consist of men only, each man having a rifle, a bayonet, a blanket, etc., but where heavy machine tools and special equipment are required, the conditions are entirely different. Groups for handling this equipment will have to be more or less permanent, and then we obtain the small-order department recommended.

The author agrees with Mr. Coes's remarks relative to obsolescence being a factor that must be reconciled by both management and consumer.

Progress in Materials Handling

Contributed by the Materials Handling Division

Executive Committee: G. E. Hagemann, *Chairman*, M. W. Potts, *Secretary*, R. H. McLain, F. D. Campbell, C. D. Bray, and E. D. Smith

IT IS IMPOSSIBLE to measure accurately the progress that has been made in materials handling during the past year. First, it is impossible to accumulate proper and sufficient data. Second, there is no real yardstick by which this progress can be measured. A questionnaire was broadly circulated in an effort to secure such information as would be helpful in bringing before this Division the nature and extent of the year's progress in materials handling. The replies received indicate that while there is a great deal of interest in the subject, there are yet many cases in industry where there seems to be little, if any, attention paid to it. The manufacturers of materials-handling equipment seem to be making real progress, and in several cases are doing special research work.

While most manufacturers of materials-handling equipment are conducting their own experiments, much is also being done with the cooperation and assistance of industry. For example, a certain industry will present a problem to a manufacturing company and will agree to work out as far as possible the materials-handling problem. In some cases this may present many mechanical and structural difficulties. The job is then built with the understanding that it will take some time to get the various problems solved. This has been particularly true with the automobile industry. Research work is being done to some extent, in colleges and in testing laboratories, along the lines of heat-resisting alloys for materials-handling apparatus passing through ovens at high temperatures, heat-resisting bearings, and the effect of combinations of water and heat. Lubrication problems, which are very important factors, are being given a great deal of attention and study by both the conveyor manufacturers and the lubricating companies.

Manufacturers of materials-handling equipment report increasing interest on the part of industry, stating that they are now frequently called into consultation when plans for changes or additions are in very early stages so that the scheme or plan under consideration may be developed with particular reference to proper materials handling. They report also that the increased output per unit of machinery has been a big factor in making proper handling methods a necessity. Another very important development seems to be the fact that the average manufacturer now has generally gotten away from the thought that his product could not be handled on chains or conveyors because it was "entirely different."

Clay Products

The tremendous increase in the cost of common labor compelled the manufacturers of clay products to seek mechanical replacement of common labor if the cost of their products was not to become prohibitive. While there has been no organized research work on the subject-matter, the clay-products manufacturers, their engineers, superintendents, and foreman have all engaged in the study of mechanical handling in an effort to reduce labor costs. Manufacturers of clayworking machinery and mechanical-handling engineers, of course, have aided in solving the various problems. Steam, gas, or electric locomotives and cars have replaced the mule carts that brought clay from its source to the plants, conveyers have replaced wheelbarrows in the plants and shipping yards, and tractors convey the finished product, deliver coal to the kilns, and remove ashes and waste material.

With every manufacturer and his working forces assisted by competent mechanical engineers engaged in research study, the clay-products industry has progressed more in the matter of materials handling during the present century than during several hundred years previously, and is now entitled to a very favorable rating as a mechanically equipped industry. These companies report also that savings in labor costs have been large and that the research work is continuing.

Railroads

Several of the roads surveyed have made elaborate studies of the problem of handling and transporting parts and material. Electric hoists on individual cranes and additional installations of traveling cranes have served to reduce handling of parts in process of manufacture or repair in the main shops. Motorized delivery systems have been installed to place material at the point of use and have served to eliminate the expensive and time-consuming method of handling parts by manual labor. In many shops electric platform trucks are now used to handle parts and materials that are loaded on skids.

Undoubtedly the development of the "spot" system of car and locomotive repairs has been the most important influence toward the increased utilization of materials-handling equipment. With this system, both locomotives and cars are moved through the shop from station to station. Only certain kinds of work are performed at a single station. The various parts are routed from the first station to the various repair departments, where they are overhauled and then moved to the proper station on the erecting floor. Lift platform trucks with skids have been found to be advantageous in connection with the spot system of locomotive repairs. In the case of car repairs under the spot system, crane trucks have been found very useful. In fact, several of the Class 1 railroads prefer crane trucks for car-repair work to overhead traveling or gantry cranes.

An interesting development in both car and locomotive repairs, especially coach repairs, has been the increased utilization of the overhead monorail. The railroads, being a transportation industry, are not organized to any important extent to carry on research and development work, and as a result have to depend almost entirely on the developments of materials-handling equipment made by the manufacturer. Railroad mechanical-department officers indicate, however, that they recognize the possibilities of substantial economy through the use of modern materials-handling methods.

Packing Industry

There were a number of developments in packing-house processing during the past year. Gasoline tractors have been designed which have the approval of the insurance companies for use under packing-house conditions. Formerly electric tractors were used, necessitating large rooms for recharging the batteries. The gasoline tractors have eliminated the need of these rooms. A scale used quite extensively in the weighing of coal from coal mines has been adapted to packing-house requirements, auto-

matically records the weights of products upon a tape, and does away with a scaler. A truck has been perfected that will handle conveniently a very much larger quantity of packing-house produce from departments or assembly rooms directly to the cars. This truck has supplanted a number of laborers and has speeded up the operation of loading. A saw has been perfected which will split the entire backbone of a beef carcass. This saw does the work very much more rapidly than was possible under the old method of hand splitting. Furthermore, skilled workmen are difficult to obtain for this operation. Insulated and refrigerated

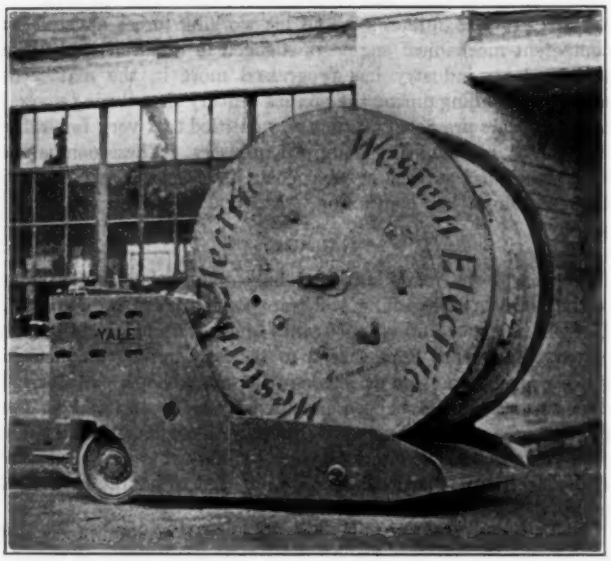

FIG. 1 NEW REEL-CARRYING TRUCK OF 10,000 LB. CAPACITY

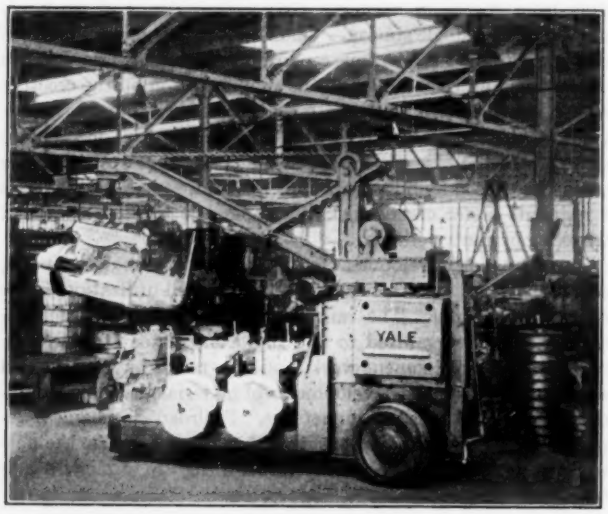

FIG. 2 6000-LB. LOW-PLATFORM, LOW-LIFT ELECTRIC INDUSTRIAL TRUCK WITH 1500-LB.-CAPACITY CRANE

meat trucks for delivery of meat products direct from packing houses to retail stores are finding increased use. These trucks are making deliveries to points at least 200 miles distant from the packing houses. Their use has eliminated several handlings of packing-house products required under the old system of delivery either by express or by peddler cars. Increasing interest is being manifested in railway refrigerator cars refrigerated by the silica gel system. If adopted, this method would eliminate the present need of icing stations along the route of shipment.

INDUSTRIAL TRUCKS

Fig. 1 shows a new 10,000-lb.-capacity reel-carrying truck. It is of the six-wheel type, having, in addition to the regular drive motor, a separate motor-driven unit which operates two

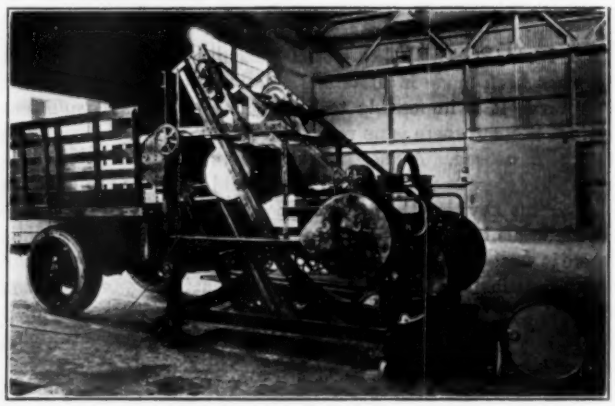

FIG. 3 PORTABLE BARREL AND DRUM LOADER FOR ELEVATING FILLED DRUMS FROM SHIPPING FLOOR TO TRUCKS OR CARS

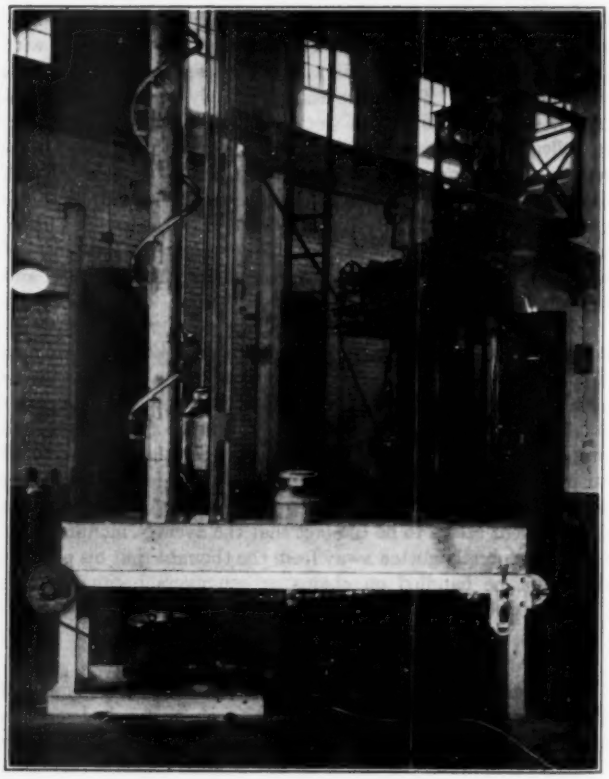

FIG. 4 DISCHARGE SECTION OF CAN DESCENDER

cables over a drum and idler sheaves. The truck approaches the cable reel and the pulling unit is set in reverse, allowing the cable to run out on each side. It is then fastened to a spindle, which is run through the reel, and the lever is thrown so that the pulling unit draws the reel toward the truck. The back end of the truck rests on the ground when the reel is not on the platform. The

action of the reel rolling past the center of the pivot in this platform causes the platform to rise into the position shown in the photograph. In this manner, very large and heavy cable reels are transported rapidly and with very little labor.

Fig. 2 shows a 6000-lb. low-platform, low-lift electric industrial truck upon which is mounted a 1500-lb.-capacity crane. This truck is primarily a low-lift skid-carrying truck having a platform lift of $4^1/_2$ in. The truck is shown with its own platform loaded, having been loaded by the crane, and an additional load on the crane hook. The articles shown being transported are marine engines, and it was not found necessary by the user to make use of skids in the transportation of this material.

Fig. 3 shows a portable barrel and drum loader for elevating filled drums from the shipping floor to trucks or cars.

FIG. 11 MULTI-RUNWAY TYPE OF OVERHEAD CRANE

Fig. 4 shows a milk-can or ice-cream-can descender that has been developed and is used as a power descender to convey filled or empty milk cans or ice-cream cans from upper to lower levels. In ice-cream plants very often the freezers are located on upper levels and it is necessary to lower the can of frozen cream from the freezer to the hardening rooms below. This type of unit fits into this need very completely.

The newly developed high-lift truck for the purpose of icing pullman dining cars has been recently placed in service at Buffalo. Using this truck, two men can ice 18 dining cars in $2^1/_2$ hours, whereas it formerly took 6 men 8 hours each to ice 15 cars. This truck has a high body which lifts up, loaded with ice, to the height of the dining car. It is only necessary for the men to put the ice into the icing compartment. The body can then be lowered from a controller located on the high-lift body.

This year there has been brought out a truck, the battery of which is mounted above the deck directly over the front wheels next to the dash. In this position it acts as a counterweight for the overhung loads for which this machine was designed, i.e., cranes with extensible topping-lift booms, and for the vertical elevating mechanism on which can be mounted shovels, crane arms, rams, stacking tables, and devices for stacking both cylindrical and rectangular packages. The mounting of these various devices is so made as to permit changing from one to another in a couple of minutes. This machine has the same wheel units, power units, steering mechanism, and control as were used on the older line, and these are therefore interchangeable between the two types of truck. The new trucks are made in three sizes, having 36-, 48-, and 60-in. wheelbase lengths. When equipped with a telescopic topping-lift boom, there are two power units mounted over the battery, one for raising the boom and the other for hoisting the hook. When so equipped they will handle 3600, 4800, and 6000 lb. at high speed over ordinary street pavements or on cinder-filled yard areas. To change from the shovel to the ram or any of the other tools used with this machine, it is necessary only to cast the rope off the equalizing bar and pull out the hinge pin at the bottom of the crosshead.

A similar elevating mechanism has also been brought out in the form of an attachment to the jack-lift truck which has been made for years. This attachment automatically locks to the frame of the truck, and then the jacks raise the attachment to the operating position in exactly the same way as the crane attachment which has been used with this truck for years.

Among the interesting jobs which these trucks have done this past year are the complete handling, mechanically, of freight on one of the Brooklyn, N. Y., piers. The use of hand trucks has been entirely eliminated on this pier, and the savings have been very substantial. At Barranquilla, Colombia, S. A., it has been found that, in spite of the fact that very cheap native labor is available, the two trucks which are used for handling the freight between railroad cars and storage and the shallow-draft river boats, have been paying for themselves every three months.

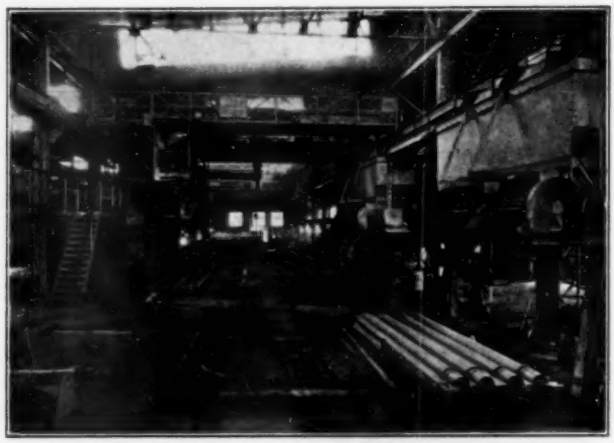

FIG. 12 FOUNDRY ARRANGEMENTS FOR CASTING IRON PIPE HORIZONTALLY

A new truck has been developed known as the foot-lift truck. This truck enables the operator to elevate the load by using the full weight of his body, rather than calling into play his back and stomach muscles, which are used when the load is elevated with the steering handle. The foot pedal is so designed that it automatically engages with the load-elevating means when depressed, and automatically disengages when it is returned to normal operating position. The room required to operate this truck is much less than with any other type, as it is necessary only to provide sufficient space for the operator to stand in front of the truck, whereas on the handle type it is necessary to have aisle room to bring the handle practically to the floor in raising the load.

Where standard box skids are used for handling material through machine processes by means of a jack-lift truck, the "Jack-Rack-Stack" system shown in Fig. 5 has been successfully used. For storage, they are racked with the electrically operated stacker shown in the illustration. Units weighing from 1000 to 2000 lb. are easily handled in this way by one operator. A saving of space is at once apparent, as the five tiers of skid boxes are handled from a single aisle.

Fig. 6 shows a new tier lift truck which has recently been developed. This truck has a motor-driven winch mounted at the rear of the elevating platform for loading dies and other heavy

material on the truck. This mechanism raises and lowers with the elevating platform.

Fig. 7 shows a recently designed machine for handling steel drums. The drums are loaded in box cars with this machine and are taken out of cars and stored two high in the warehouse. There has been a great saving in labor through the use of this particular machine, as the drums illustrated are filled with a paste used for making storage-battery plates and consequently are very heavy. Formerly one man was required to handle one

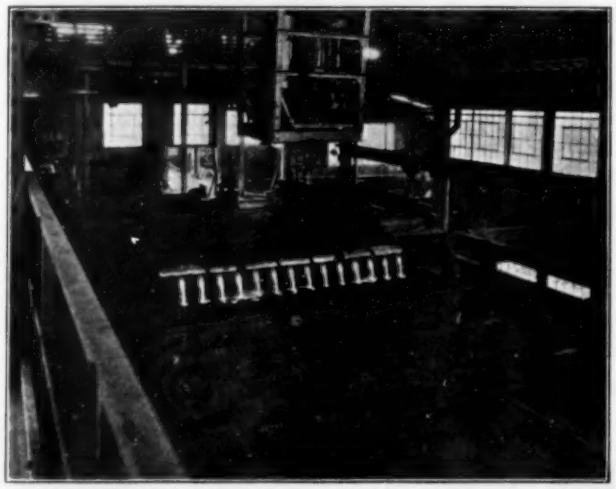

FIG. 13 MULTIPLE-LIPPED LADLE FOR POURING METAL IN HORIZONTAL PIPE MOLDS, AND CRANES FOR HANDLING FLASKS AFTER THEY ARE SHAKEN OUT

FIG. 14 MOTOR BRACKETS HANDLED ON VERTICAL SPINDLES BETWEEN MACHINING OPERATIONS

drum at a time, while the new machine is built to handle four drums at three times the speed of the man with the hand truck.

Fig. 8 shows what has been developed within the past year in the way of a gantry crane which can be moved with ease sufficient to warrant its use in a great many machine shops throughout the country. This crane has ball bearings on both the lower leg and also on the overhead half of the crane, and is so light and so designed that one-ton or two-ton loads can be picked up by the electric hoist at any point on the crane, and the entire crane moved by pushing on the load.

The "hairpin-hook flipping device" shown in Fig. 9 has been developed to supplant the practice, usual in wire mills, of moving material through the plant on floor-operated trucks, then removing each coil of wire from the truck and placing it on the reel before the wire is drawn. A flipper is installed on the end of a hairpin hook, and by properly applying this flipper, wire can be moved through the mill on a hairpin hook of this size in quantities of about 3000 lb. to the hook, and these hooks pushed in front of the wire-drawing benches, as shown in the figure, where the wire is flipped off the end of the hook without rehandling in the wire mill. The first installation of this kind was completed this last summer.

CRANES AND CONVEYORS

Fig. 10 shows a power-operated transfer bridge which is the result of several years of experiment in an effort to develop a transfer bridge which will lock at both ends with discharge points, and permit the hoist to move off either or both ends, as the case may be.

Fig. 11 illustrates the development of the multi-runway type of crane. The advantages of the three runways lies in the fact that by dividing the span of the crane in three sections, a much lighter crane can be furnished for a given load, with the result

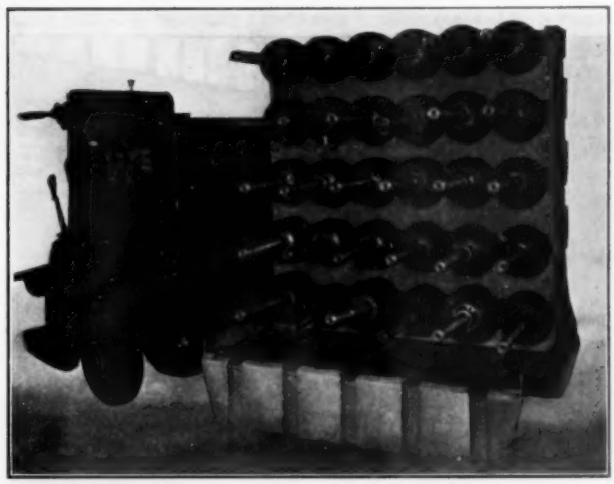

FIG. 15 INDUSTRIAL-TRUCK SKID WITH SPECIALLY DESIGNED RACK FOR HANDLING ASSEMBLED MOTOR ROTORS

that the weight of the crane is reduced to a minimum. This reduction is a decided advantage in connection with the use of hand propulsion, because there is less deadweight to handle. The lighter cranes also have a decided advantage from the standpoint of building construction, because, with the use of the three-runway or multi-runway type of crane, the weight of the crane itself usually does not exceed the load which it is designed to carry.

A rapid and extensive use of conveyor-type systems for electroplating and deposition of metals has been reported. Estimates made by the manufacturers of this equipment indicate in many cases that the labor is cut 20 to 25 per cent, and at the same time the material is transported from one point in the plant to another for the next operation. When such a system takes the place of the old still-tank plating, the floor space is only a fraction of what was previously required and there is an almost complete elimination of the very sloppy condition usually prevailing in plating rooms. Another significant development in the metal-working field is the handling method adopted by the manufacturers of tinplate and sheet steel, who are loading this material into freight cars on standard skids by means of storage-battery industrial trucks so that the recipient of these goods at the other end of the line can unload them from the same skids with the same type

of truck and effect a tremendous saving in the handling cost.

A manufacturer of automobiles has adapted the fork-type truck to select bodies of the correct color to fit the specification of the chassis on the assembly line. Previously bodies have been taken from the conveyor horizontally, mechanically tilted on the cowl end, then revolved, picked up by a truck, and finally stood on end. The new method has reduced storage 66 per cent and has saved an investment of $250,000 which had been appropriated for new storage warehouse.

Fig. 12 shows a somewhat unique development in foundry handling. In the foreground of the picture there are patterns for four cast-iron pipes in one flask. These pipes are cast horizontally instead of vertically as is the usual custom. Furthermore, they are cast in green sand and with green-sand cores. Fig. 13 shows a multiple-lipped ladle that is used for pouring these pipes, and also the cranes which handle the flasks after they are shaken out.

A railway car and foundry company reports the recent development and installation of labor-saving devices, the most outstanding one being a "wheel breaker" used in breaking old wheels which are to be charged into cupolas at the foundry. These wheel breakers have now been developed to the point where they

FIG. 16 TRUCK FOR HANDLING COMPLETE MOTOR PARTS FROM STORAGE TO ASSEMBLY LINE

are practically automatic and have reduced the number of men required for this work from five to one, or at the most, two. The company is planning the installation of a chain conveyor for delivering the broken wheel sections from the breaker to the cupola charging platform. This step is expected to result in a further elimination of three more men.

The materials-handling installation made at a motor-car company's plant in Detroit in connection with a new forge shop for crankshafts is of interest in that it is among the first attempts to put forge-shop production on a continuous basis. This development has been made possible largely through the medium of materials-handling equipment. The crankshaft forge shop is laid out for straight-line, continuous production, with no stock of parts at any operation. Travel of the metal from the original bar stock, through all processes, and finally into the railroad car for shipment, is handled by various conveyor systems. There are five forging units, three heat-treating furnaces, and two pickling machines. This equipment handles 7500 crankshafts a day. The time required to convert bar stock into crankshafts, delivered at the shipping platform, is only $4^1/_2$ hours. In all, 225 men are employed in this new forge shop. The success of this development, and the reduction in total costs of forging it has brought about, open the way for the extension of the idea to other forged parts produced in quantity.

At another plant in Toledo, Ohio, a materials-handling installa-

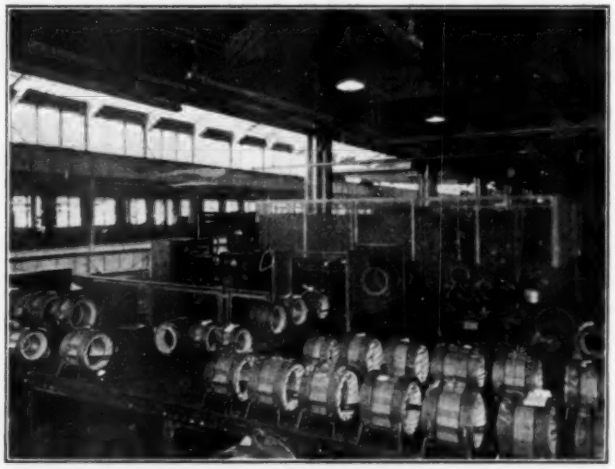

FIG. 17 POWER-DRIVEN CONVEYOR USED IN TESTING WOUND MOTOR STATORS

FIG. 18 NEW CRANE GRAPPLE WITH POWER OPENING AND CLOSING AND POWER SWIVEL FOR HANDLING LEAD-COVERED-CABLE REELS WITH AN OVERHEAD CRANE

tion was made which has revolutionized the manufacture of transmissions at the plant and reduced the floor space required for the output to about one-third of the former area.

Materials-handling developments at the East Pittsburgh plant of an electrical-equipment manufacturer have been along the

line of special equipment made to fit some certain job. This may or may not fit in with other standard materials-handling equipment, such as conveyors or industrial trucks. In attacking many of the problems in this plant, where so-called standard methods of materials handling cannot be applied, careful study usually shows a method of meeting the problem which results in lessened handling costs. Industrial electric trucks are being applied to an increasing extent, and with definite advantages on many lines of work. The flexibility of the truck is so great that it fits in excellently with the needs of such a plant, where the line of work varies from a small screw-machine part to a generator as big as a house. By using the trucks as a motive power for industrial trailers in addition to their own pay load, the company has effected considerable economies, and has also taken care of peak-production loads without the addition of extra truck equipment.

Motor brackets are handled on spindles between operations performed on automatic machines, as shown in Fig. 14. These occupy little floor space and may be adapted for quick handling by means of chain conveyors.

The adaptation of an industrial-truck skid with a specially designed rack for handling assembled motor rotors is shown in Fig. 15. This method keeps the rotors clean and free from damage and allows bulk handling from and to storage.

Fig. 16 shows a truck handling a number of complete motor parts which are secured from storage and conveyed to the assembly line. From the truck they are placed on a power conveyor where final assembly and test are made.

A power-driven conveyor used in the testing of wound motor stators is shown in Fig. 17.

A New Jersey manufacturer reports the use of a new crane grapple with power opening and closing and power swivel for handling lead-covered-cable reels with an overhead crane, shown in Fig. 18. This grapple eliminates the necessity of having a floor man to insert the plugs in the hub centers.

This company also reports the employment of all-water shipment of bare copper wire from Hastings, N. Y., to its plant at Kearny, at a marked saving over rail or truck shipment. This method involves the use of several hundred new box skids, seven flat cars in the yard, and a high-lift electric truck. With the exception of a manual inspection operation, the wire is not touched until it is unloaded at the insulating machine.

Skid Shipment

The Department of Commerce reports that this method of shipment has continued to grow, as well as the use of various types of containers for rail and water shipping. In some cases skid shipment has shown a very remarkable saving, one large paper company reporting a reduction in labor costs of 90 per cent.

MH-52-2

Fundamentals Which Should Be Observed in Design and Application of Tramrail Systems

By E. T. BENNINGTON,[1] WICKLIFFE, OHIO

The design of overhead conveyors and tramrail systems has gone through its period of expansion, change, and improvement with the results that this type of machinery is playing a very important part in a great many intensified and concentrated production schedules, and it is the expectation of those that are following the development of this business that it is destined to play a far more important part in the very near future.

There are many fundamental principles of design for overhead-conveying machinery that cannot be safely overlooked if a system is to be subjected to severe service. Even if it is not to be subjected to severe service, from the standpoint of safety and ease of handling, these principles should all be understood and observed. This paper contains only a few of the more important principles of design and application.

FIG. 1 RESULTS OF PEENING ACTION ON AN ORDINARY I-BEAM

NO SYSTEM using a rail of improper design can be operated successfully, for the backbone of any conveying system is the rail. There are several very satisfactory ways in which to provide a rail that will give proper service and will not be rendered useless by "peening," that enemy of every rail system, whether it operates overhead or on the ground. The ability to relieve peening is what determines the life of an overhead rail and a railroad rail; it is what determines the life of a floor made of steel plate such as is used in steel mills; and it is what determines the life of all overhead systems.

The results of the peening action can be described by reference to Fig. 1, which is an ordinary I-beam such as was used rather commonly in the past for overhead systems. The constant rolling of the wheels on this beam causes that part of the beam that comes in contact with the load-carrying wheels to peen or expand in all directions. When this expansion takes place, the metal thus moving must go in some direction, with the result that the flange must turn down as shown, because that part of the flange of the beam which is directly beneath the flange carrying the load-bearing wheel is not subjected to a similar expanding action, and consequently remains in its original position.

For many years it was thought that the reason for the flange turning down was because the rail had been overloaded. This theory has long been exploded. If an overload were to cause the flange of the beam to turn down, the flange of the beam would turn down the first few days that such a system was in service, but it has been learned in actual practice that the turning down of the flange does not occur for a considerable period after the system is installed and until it has been subjected to a great many passages of load-bearing wheels.

There are only four ways known to the author to provide a rail for an overhead system that will not be rendered useless in a short while by peening. Fig. 2 shows an ordinary I-beam provided with railroad rails attached to the lower flange of the beam, the wheels running on the rails and not on the beam. Fig. 3 shows what is known as a Pencoyd section that has a special wedge-shaped strip-steel member riveted with countersunk rivets to the lower flange of the beam. This design enables the rail to be installed with curves of somewhat shorter radii than that shown in Fig. 2. If wedges of the proper size for the load to be carried are used, this will make an excellent system, and can be subjected to the very hardest kind of service.

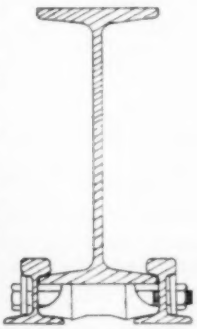

FIG. 2 RUNNING RAILS ATTACHED TO LOWER FLANGE OF I-BEAM

FIG. 3 SPECIAL WEDGE SHAPED PIECES OF STEEL RIVETED TO LOWER FLANGE OF I-BEAM

Fig. 4 illustrates the new type of I-beam that has been developed by several steel mills, and that has flat flanges to which strips of steel can be welded or riveted which will make a good overhead carrier. Fig. 5 illustrates the type of rail used by one manufacturer specializing in the construction of tramrail systems. This is rolled in one piece, and made of high-carbon steel. It provides a flange that will not be distorted by peening, although peening still takes place the same as it will in all of the shapes and suggestions offered in the previous figures. In all four types illustrated the metal which is peened or expanded works off the rolling surface in the form of the flange without distorting the shape and without rendering it unfit for continued use.

FIG. 4 I-BEAM WITH FLAT FLANGES

THE SWITCHES

There are two types of tramrail switches which are used, the

[1] Manager of the Cleveland Electric Tramrail Division, Cleveland Crane & Engineering Company.

Contributed by the Materials Handling Division for presentation at the A.S.M.E. Akron Meeting, Akron, Ohio, October 21 to 23, 1929. All papers are subject to revision.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tongue-type switch and the transfer switch. The tongue-type switch is the cheapest to build, and is satisfactory only when used in connection with tramrail systems employing carriers that are hand-pushed along the rail. This type of switch should not be used with electrically propelled carriers because of the impact caused on entering the switch. The design is such that a bad rail connection cannot be avoided at the hinge of the switch, and the direction of the load is changed suddenly at the same point. For this reason a severe impact is thrown into the system as well as the carrier if the electrically propelled carrier is traveling at the usual speed for such devices.

The transfer-type switch shown in Figs. 6 and 7 provides a smooth path through which the carrier can operate. The rail over which the carrier passes will bend to a very short radius, nevertheless there is no obstruction or wide gap that will cause impact, and it is for this reason that nothing but the transfer-type switch should be used when power-driven carriers are selected.

On systems using hand-propelled carriers which are to be subjected to hard service, the transfer switch will be found to reduce maintenance costs and improve operating conditions. The transfer switch is often justifiable when used in connection with applications of this sort.

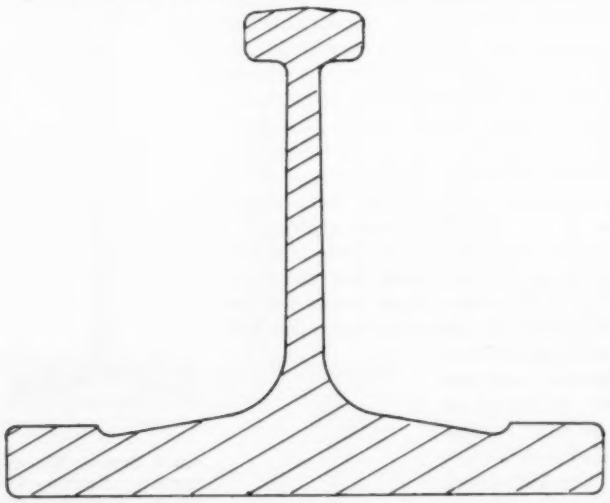

FIG. 5 RAIL ROLLED IN ONE PIECE

HAND-PUSHED CARRIERS

Without question so-called anti-friction bearings of some kind should be used on all hand-propelled carriers. It has been noticed that all manufacturers of these carriers are coming to the use of ball bearings although some types of roller bearings will provide good operating conditions. As users of tramrail systems are requiring more and more in the way of flexibility for the systems, some wanting rail bent as short as 18 in. radius, it is necessary to have the carriers designed with a long wheelbase, and with wheels that swivel independently on each end of a long load bar. (See Fig. 8.) The long wheelbase enables the carrier to negotiate curves with less tendency to bind and jerk, and the swivel ends permit natural movement of the flanges of the wheel and prevent digging into the rail on short curves, which always occurs if the four wheels on the carrier are locked rigidly together.

ELECTRICALLY PROPELLED CARRIERS

An electrically operated carrier that is not properly designed and constructed will not only be a source of high mechanical repair expense, but is likely to represent a real hazard to the operator and others. (See Fig. 9.) There are some fundamentals of design that should be embodied in every electrically propelled carrier that is put in service. Such a carrier should have the operator's cab separately supported from that part of the carrier that carries the load. The practice sometimes followed of carrying the operator's cab from the main body of the hoist is to be severely condemned.

It is not uncommon for an operator to try to pick up a load that is either attached to the floor or that is held in place by sticking or shifting of piles with the result that the lifting effort is many times that for which the carrier is designed, and something gives way. If it is a king pin, a wheel pin, load bar, or hoist, the operator suspended from the load-carrying member will surely drop with that member, whereas if he is separately supported on the rail, the rail itself must break before he can be injured. There is little likelihood of his ever reaching the ground as the rail is always the strongest member on any monorail system.

The increasing demand for high speeds and carriers that will negotiate curved rails of very short radius has brought about the introduction of spring suspension and swivel ends with two wheels only in each end. Carriers operating at speeds of 600 f.p.m. or greater could not possibly withstand hard service unless the weight were sprung. It can easily be imagined what would happen to a railroad roadbed if the freight cars were built without springs for the load; the cars and roadbed would be pounded to pieces in a very short while, and the same thing would happen to an overhead-conveyor system regardless of the kind of material from which it is constructed. The demand for high speeds has made the use of springs imperative, and they were unheard of eight years ago.

Swivel heads are of equal importance when curves of short radius are encountered in the rail. If all four load-carrying wheels were locked together, the flanges on the wheels would cut away the rail on the inside of the curves even though the wheels were located very close together.

Another very important fundamental design that should be incorporated in every electrically propelled carrier is the feature of long wheelbase, as the greatest practical and possible distance between the wheels that carry the load. Strange as it may seem, the long wheelbase has a remarkable influence in preventing a load suspended from the hoist from swinging out of control when negotiating a curve at a lively speed. This feature of long wheelbase is just as important to the electrically propelled carrier as it is to those that are pushed by hand.

FUNDAMENTALS OF APPLICATION

Every successful installation of material-handling machinery is successful because it does one of two things. It either eliminates rehandling operations or it permits the handling of more material each trip. There are many who have a great deal of faith in what can be accomplished through the use of these two fundamental principles as applied to overhead conveying, but there is also the large majority of engineers who have not yet come to realize the real advantages in store for them through proper use of these principles of overhead-conveying machinery.

The savings and advantages do not lie alone in reducing the cost of the payroll for the men actually engaged in the moving of materials. The application of these principles has usually a far-reaching effect. It has been known to affect the operating costs in every department in some of the largest plants in the country.

As an example of elementary rehandling operations Fig. 10 shows the handling of coils of wire in a large steel mill. There are 3300 lb. of wire on the hook made up of 11 bundles weighing 300 lb. each. Before the installation of the tramrail system shown, there were 20 men employed in the handling of this wire rod as it came off the mill. It was rehandled many times before it entered the manufacturing department or was placed on cars.

As it came off the mill it was put on trucks, one bundle at a time by hand, then the truck was either pushed to the storage yard or to the cars for shipment as wire rod. If it was to be

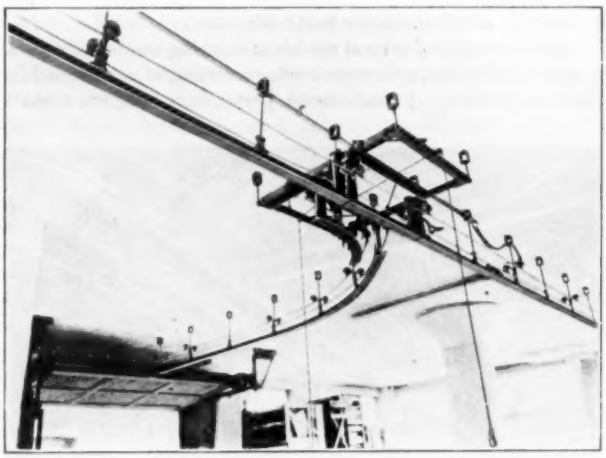

FIG. 6 THE TRANSFER TYPE SWITCH PROVIDES A SMOOTH PATH FOR THE CARRIER

loaded on the cars, the truck was pushed to the side of the car, and each bundle was hoisted by hand to the inside of the car, and after reaching the inside of the car it was again moved by other men to its final position inside the car for shipment.

By the introduction of a properly planned tramrail system, the bundles are dropped in a long row from the cooling conveyor, standing up about as they are shown resting on top of the car in the illustration. The rail being suspended over this row, the operator has but to cause the hairpin hook to be lowered to the proper elevation, and then move the carrier forward until the hook is inserted its full depth into the coils. Then the hook is raised until the load is clear of the ground, and the carrier is moved over the car, where the load is deposited in its proper place.

A conception of the relative capacity of hand labor aided by trucks and the hairpin hook unit on the tramrail system can be obtained by considering that the capacity of 20 men and a few trucks was 200 tons loaded into cars per day, whereas one unit is capable of loading 900 tons per day if the capacity of the wire mill were such that this amount of material could be produced and to enable the operator with the carrier to be employed constantly.

This is a good example of what a properly planned tramrail system will do, but it is not by any means an exceptional example. There are hundreds of installations made about the country each year which have effected equal results in proportion to the cost. Some of the indirect savings resulting from an application of this kind are elimination of tangled bundles, as they are not handled so often, and they arrive in the manufacturing department in very good shape, thus reducing the non-productive time on the machines while the bundles are being untangled.

When hand labor was used, it was not uncommon for the mill

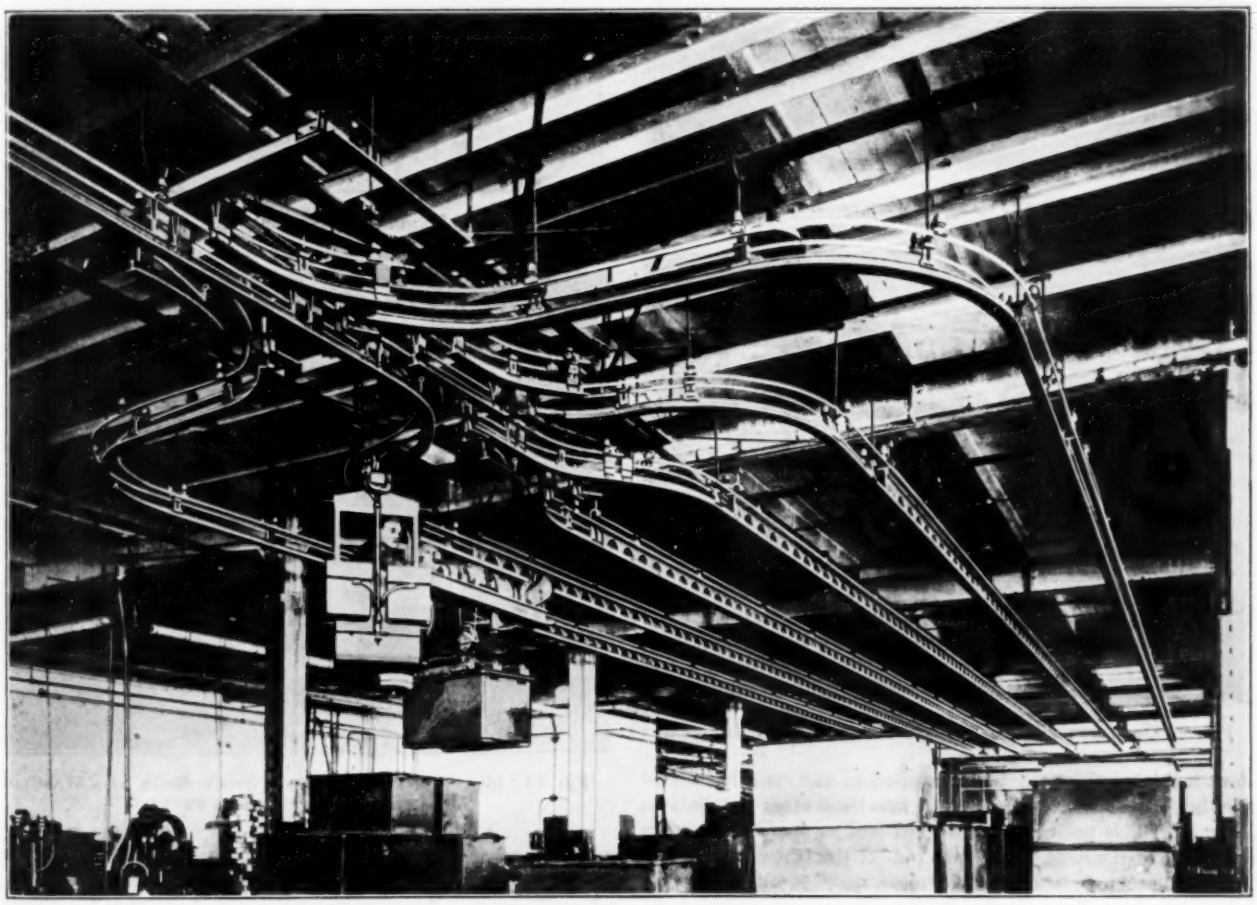

FIG. 7 SHORT-RADIUS BENDS ARE OFTEN NECESSARY

to run ahead of the handling crew, with the result that the mill had to be stopped occasionally until the congestion was removed. This congestion has never occurred since the tramrail system was installed.

It would undoubtedly be interesting to discuss similar installations involving this principle as applied to various other industries but space will not permit going into these other installations in detail. This principle has worked just as successfully when applied to textile mills, paper mills, rubber-tire factories, bolt and nut manufacturers, fence manufacturers, metal furniture, electric-refrigerator factories, potteries, machine shops, and many others.

Fig. 11 shows how more material may be handled each trip. The stock room of an electric washing-machine manufacturer is shown. Before installing the tramrail system, the usual type of stock room was used consisting of long rows of bins in which the smaller parts were kept, and four-wheeled trucks cluttered all over the place in which the larger parts were kept.

In the assembly of several models of washing machines, several thousand different parts were used, consisting of screw-machine products, castings, pressed-metal parts, bars, angles, motors, switches, etc. The material was withdrawn from this stock in the usual type of tote box of a size that would hold about 50 lb. of small screws. As an operator ran out of material his supply was replenished in containers of this size or in bundles of angles,

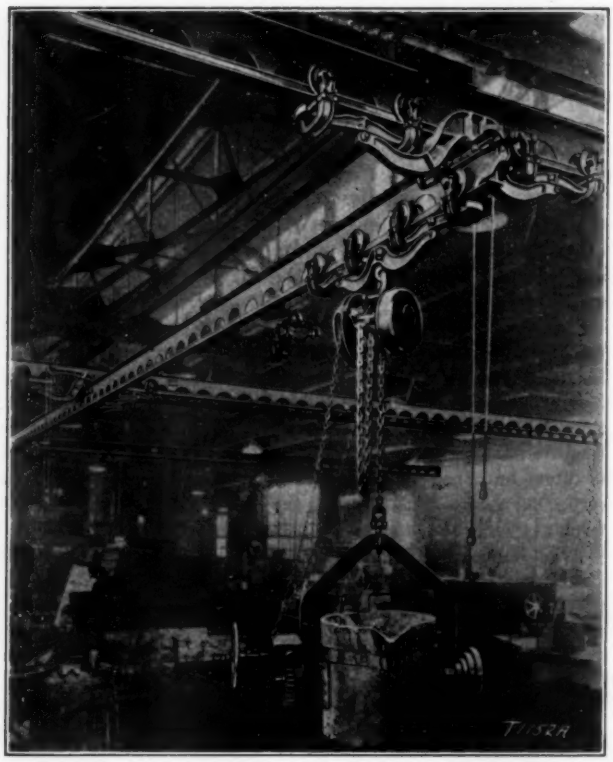

FIG. 8 HAND-PUSHED CARRIER WITH LONG WHEELBASE

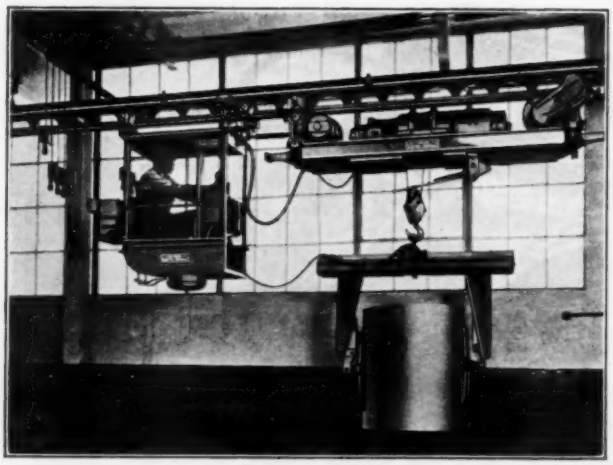

FIG. 9 OPERATOR'S CAB SUPPORTED SEPARATELY FROM CARRIER

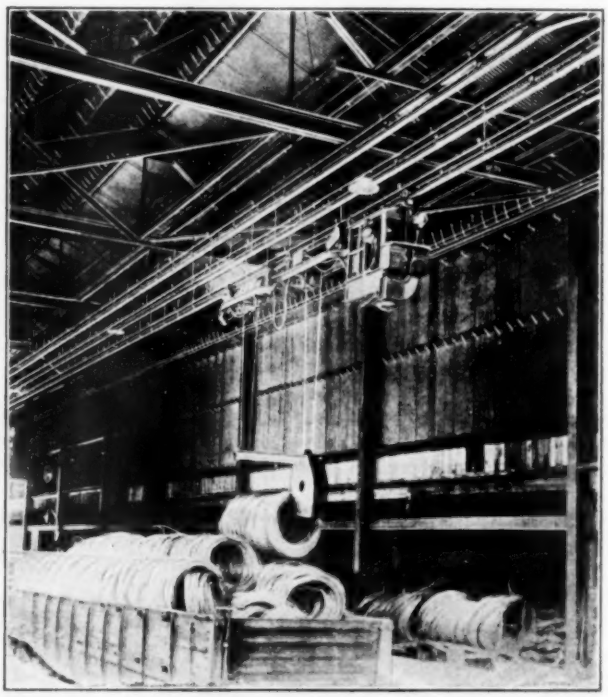

FIG. 10 HANDLING WIRE COILS IN A LARGE MILL

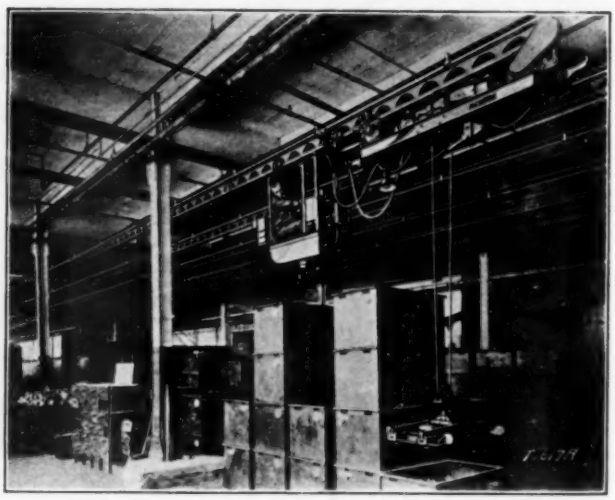

FIG. 11 MATERIAL HANDLING IN A STOCK ROOM OF A WASHING MACHINE MANUFACTURING PLANT

rod, etc., depending upon the nature of the material being used at that time.

If the stock of only one small part should unexpectedly become depleted, no more machines of this model could be assembled until the supply was replenished. This manufacturer took the first step toward successful handling of his material when he established a definite stock run for each model of machine. He then purchased 300 steel containers, all of which had the same dimensions on the base and varied only in height. The cubical capacity of these containers was fixed so that there was a size to hold the exact quantity of any part required to complete the previously established stock order.

Assume that the established stock order of model X machines was 500. The purchasing department would purchase the various parts required in the quantity that provided the lowest price.

When these parts were received, 500 of them would be put into one container if only one piece was used on each machine. If ten pieces were used on each machine, 5000 would be placed in the proper-size container as they were received and checked in the receiving department.

Where parts were too large to get into one container in quantities of 500 these were placed in two containers or five containers, and those containers plainly marked $^1/_2$ stock order or $^1/_5$ stock order to conform to the quantity they held. There were also a few cases where several kinds of very small parts were grouped into one container. These were parts that did not require any manufacturing operations before assembly. They were placed in this container in such a way that they did not become mixed up but were separated from each other by partitions.

Those parts that did not require manufacturing or finishing were moved to the machines as the schedule of each department permitted, and after the completion of the machine operation they would be moved back into stock to await assembly. This relieved floor congestion in the manufacturing department.

Aside from the saving effected in handling large units at one trip, and eliminating rehandling, the inventory system, cost system, and record of material lost in manufacturing operations could be more accurately accounted for. Since a tramrail system was employed to handle these containers with a special automatic grab that enabled the operator to attach or detach the load from the cab without the aid of any one on the ground, these containers were piled four or five high, and aisle space was entirely eliminated. The capacity of the stock room was increased about 400 per cent, and the cost of a new building which would otherwise have been necessary under the old scheme of things was saved entirely.

It has been the author's observation that fully 80 per cent of the manufacturing plants that are not accustomed to the use of material-handling machinery, and particularly overhead machinery in large ways, do not begin to realize the savings that are effected through the application of these two principles of handling materials. It is true that it is difficult for any engineer to determine definitely just how great these savings will be. It is one of those things for which no definite plans will probably ever be developed for calculating purposes because of the various conditions encountered in the plants, but it is not difficult to go back after these principles have been adopted by some manufacturer, and compare the cost under the new scheme of things with that existing before application of these principles.

MH-52-3

Incentive Payment Plans for Material Handling

By C. A. FIKE,[1] EAST PITTSBURGH, PA.

In this paper the author describes the methods used in installing incentive payment plans on two different phases of material-handling activities at the East Pittsburgh plant of the Westinghouse Electric & Manufacturing Company. The first phase is that of industrial electric trucking, the other is a material-supply group in the motor-manufacturing department. Detailed formulas used in the installation are included.

MATERIAL handling presents a fertile field for wage incentives. No appeal is stronger than that to the pocketbook, especially when made to workmen on this type of work where there may be small opportunity to create interest or enthusiasm due to its monotonous nature. Such work usually appeals to a certain type of workmen, but unfortunately this type is not often a production man, and unless interest is aroused in some manner, the entire production-line efficiency is affected. However, if an incentive is placed on the work, and the worker realizes that output affects the sum of money he receives in his pay envelope, the results are often astonishing; output per man increases, labor turnover is lessened, and it is no longer difficult to keep men on the monotonous jobs. In jobs where heavy physical effort with slight mental energy is the requirement, the results are the same.

The primary cause for an incentive wage-system installation is to increase manufacturing efficiency by supplying a reason to the worker for taking full advantage of all facilities provided, as well as a stimulant for increased personal efficiency, both through mental and physical effort. The worker provided with such an incentive will make effort to avoid delays, rather than invite them as giving an opportunity for a rest, and where some delays are unavoidable, will exercise his ingenuity to minimize them. The increase in earnings brought about in such manner attracts and holds a better type of worker.

In placing an incentive on material-handling work, considerable preliminary work must be done, especially if it is on work which is entirely new to such procedure. If it is the latter type, effort should be made to pick out that part which will most quickly and clearly show results. In other words, establish incentives on the easier jobs first, and those that are harder will not be so difficult when installation is finally started on them. Before any time studies are taken, the workers should understand what is to be done, and as far as possible how it is to be done. As a rule, if the "stage is set," in this way the worker becomes an active and willing participant in the installation, and the work is facilitated to that extent.

Securing a Measurement

In setting an incentive on material-handling work, probably the hardest thing to determine is the unit of measurement. In ordinary production work, the piece or part is usually the yardstick; such cannot always be the case on material handling. Take for example, the loading of miscellaneous material on railway cars for shipment. The pieces are unlike in size and weight, and to place separate values on each one would be impractical as the cost of clerical work would outweigh the labor savings. However, in such a case, the car weight unit can be used; cars are weighed before shipment, so the unit is available without any extra work or expense. From this it will be seen that each material-handling job must be considered as a separate problem, each with its own solution, but all based on a common principle. The unit of measurement must be understood easily, and require no great amount of clerical work or supervision in its application. Careful checking and a thorough understanding of the job under consideration will ordinarily show some logical unit which will meet these requirements.

Method of Payment

Material-handling work is usually performed by several workmen, each dependent upon the other in order to secure cooperation, coordination, and efficiency. For this reason such work can be placed advantageously on a group incentive. There are variations of this where the work may be included with a production group of men, or where the time value for material handling may be included with the production operation. If the latter case, and the production part of the work is also on a group incentive, a material handler may be included as one of that group. For example, a group of workers are dependent upon a trucker for material supply; by placing the trucker within the group, he realizes that his earnings are dependent upon keeping the group fully supplied with material at all times, and at the same time the group will aid the trucker to do his work properly, knowing that their earnings can be made higher or lower in proportion to the trucker's efforts.

The installation and operation of groups in connection with various kinds of industrial work has been pretty well covered in various papers and magazine articles, but a word of explanation may not be amiss at this time. A number of workers are placed in a group; earnings are pooled and distributed on a pay-period basis of the total hours worked by each individual in the group, times his individual rate. A simple example will illustrate this. Four men have made a total of 400 hours in a group during a pay period; A worked 100 hours, B worked 80 hours, C worked 50 hours, and D worked 170 hours. Earnings would then be distributed as follows:

$$A = \frac{100 \times 400 \times \text{Rate}}{(100 + 80 + 50 + 170)}.$$

$$B = \frac{80 \times 400 \times \text{Rate}}{(100 + 80 + 50 + 170)}, \text{etc.}$$

Provision is made for various grades of work within the group by a difference in the individual rates of the workmen, supervision within the group is taken care of by extra compensation, but percentage of gain or bonus earnings are divided entirely in accordance with work performed within the group.

Examples of Actual Installation

Two varying phases of material-handling work will be used as an illustration of what has been actually accomplished in the

[1] Superintendent of Plant Transportation, Westinghouse Electric & Manufacturing Co.

Contributed by the Materials Handling Division for presentation at the A.S.M.E. Akron Meeting, Akron, Ohio, Oct. 21 to 23, 1929. All papers are subject to revision.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

way of establishing incentives. First, that of an industrial-trucking scheme covering the entire East Pittsburgh plant of the Westinghouse Electric & Manufacturing Company, and second, the method of payment for a group handling raw and finished material in a motor-manufacturing department.

Actual figures are given, not with the idea that they can be applied to similar work in other plants, but in this way the work can be explained and understood more easily.

Industrial Trucking

Industrial trucking for the plant is centralized in one department whose responsibility is to furnish prompt and adequate trucking service on call from any production section. Trucks are controlled and service is given on a "taxicab system." Stations are established at four places in the plant in charge of a dispatcher who receives by phone or by direct word all requests for service, and dispatches trucks in accordance with such needs. Each station comprises a group, with the dispatcher as group leader. Payment is based on "loads," record of which is taken from truck requisitions made out by the section securing service. Since these same requisitions are the basis of billings for service rendered, there is slight chance of any requisition being received except those for actual service rendered.

The work performed by the time-study department preliminary to actual installation of time values involves a large amount of checking and study. The time-study write-up of this work follows in Appendix 1. Since it does not give the method of taking the time studies a word of explanation may be helpful.

Studies were taken covering all types of loading in the district covered by the group. These studies covered loading, unloading, running time, and delays. From a large number of studies, time values were selected which covered an average load under average conditions; such figures were secured for both types of trucks (platform and lift) in use as well as for trailers. These were then checked against actual figures, and approved for use as shown in the write-up.

The write-up in Appendix 2 is self-explanatory, and is a good example of similar plans in effect throughout the plant.

Conclusion

From the foregoing it will be seen that no general rule can apply to this type of work; each is a separate problem. Common sense and a full knowledge of the work involved are just as necessary as time-study engineering skill. The group plan is peculiarly fitted for such work, and averages are used to a large extent in determining values.

The number of workers required to perform this work after measurement and incentives have been established has been greatly decreased, in some cases more than 50 per cent, and when it is realized that material handling sometimes composes as much as 80 per cent of the labor content of a manufactured article, it can be readily seen that the time, training, and effort placed into such work pay large dividends both to the company and to the worker.

Appendix 1—Incentive Wage-Payment Plan for Industrial Trucks Working From North Yard Dispatch Station

Effective August 1, 1928, all trucks operating from this station, including the dispatcher and dispatcher's clerk, will be conducted on standard time-wage incentive plan by a group of twelve (12) men.

This station is in charge of the movement of material from all sections in Z building, I building, storerooms Nos. 8, 14 15, 16, 17, 18, 19, 20, 21, I-gate, and AB shipments transferred from industrial railroad to industrial truck for delivery to section.

A requisition for industrial truck service (Form No. 14284) must be given for each delivery of material, the definition of a "delivery" being any amount of material up to the maximum of one truck load which goes to one specified shop section.

The requisition will cover the delivery of the material to any point in that section, except in cases where one section is on more than one floor, making it necessary to use the elevator, the trucker should then be directed to the floor where the material is needed. In case the material has been misdirected, another requisition, properly signed, must be given the trucker before he will move it to another section. This trip will be charged against the original shipper who will be notified of same by the dispatcher.

It is imperative that material be ready with all necessary paper work attached, when the trucker reports to make delivery. In case the material is not ready, the trucker may be given a substitute load, but if no substitute load is available the trucker should be given a "No-Load" slip, and sent back to the station. An endeavor should be made, in so far as production requirements permit, to report full-load quantities destined for one section or another nearby.

For delivery of waste every Thursday, the trucker shall be given ten (10) slips, and for delivery of pay boxes, five (5) slips.

The group shall be allowed 0.336 hour for every delivery made by flat trucks and 0.252 hour for every delivery made by lift trucks.

The formula to be used in calculating the group's earnings will be $ET - TT \times F + TT = TA$

Where, ET = established time
TT = time taken
F = 0.25
TA = time allowed

Substituting the time allowances in the formula, it will read: (0.336 hour × number of flat truck deliveries) + (0.252 hour × number of lift truck deliveries) — time taken × 0.25 + time taken = time allowed.

The total number of requisitions for industrial-truck service (Form No. 14284) with the proper signatures, will be forwarded each day to the time clerk of Section L-24. At the end of each pay period a total of these requisitions will be sent to the payroll department where group's earnings will be calculated.

This wage-payment plan is subject to revision in case the conditions under which it operates are changed.

Appendix 2

Part: Stators.
Operation: Put materials in stock and supply.
Location: Sections T-20 and T-30 Group No. 1.
Std. Time: In decimal hours.

Std. Time = 0.53A + 0.60B + 0.70C + 0.78D + 0.23E + 0.30F + 0.41G

Symbols:

A = No. 200 CS stator wound and shipped from section T-20.
B = No. 300 CS or No. 12 W.W. stator wound and shipped from section T-20.
C = No. 400 CS or No. 16 W.W. stator wound and shipped from section T-20.
D = No. 500 CS stator wound and shipped from T-20.
E = No. 400 CS stator wound in section T-30 and shipped from section T-20.
F = No. 500 CS or No. 17 W.W. stator wound in section T-30 and shipped from section T-20.
G = No. 600, No. 700, No. 800 CS or type G stator shipped from section T-30.

Note: To compute group percentage, use the following expression.

$(ET - TT)\ 0.25 + TT = TA$ Then $\frac{TA}{TT}$ = group percentage

ET = Established time
TT = Time taken
TA = Time allowed

Reason for Change:

Put materials in stock added, and No. 600, No. 700, No. 800 CS and Type G stators shipped from section T-30 included.

Application:

Applies to all stators shipped from sections T-20 and T-30, and applies to group No. 1 section T-20.

Analysis:

The duties of this group begins in section S where the industrial railway leaves the loaded cars of material required in building stator cores, namely; iron, feet, end shields, frames, etc.

The loaded cars will be pushed on to elevator No. 40 and brought up to section T-20 where the materials will be unloaded and put into stock. The return material, clamps, and boxes will be loaded on the empty cars, and returned to section S, via the elevator.

Further duties of the group will be to supply the various productive groups with all material required and to load the finished stators on to shipping trays for shipment to section E-9.

Procedure:

Group (A) will bring loaded cars from section S to section T, (B) unload and put material in stock, (C) return empty cars to section S, (D) supply building group, (E) put cores into stock, (F) supply winding groups, (G) supply connecting groups, (H) move stators to high frequency test and after being tested (I) load stators on to shipping trays.

FIG. 1 MOUNTAINOUS REGION OVER WHICH A TRAMWAY IS BEING ERECTED

The Application of Aerial Tramways to Long and Short Hauls

BY M. P. MORRISON,[1] WORCESTER, MASS.

Aerial tramways are of value where no other means of transportation is possible and also in competition with other methods of transportation. The difficulties of an engineering nature are easily overcome. The advantages over other methods are independence of weather conditions, independence of ground conditions such as crossing streams, roads, ravines, and mountains, thus avoiding expensive tunneling or trestle work, and the easy protection of property by guard screens over railroads, highways, and buildings. With aerial tramways, the length and capacity are unlimited from an engineering standpoint. Tramways have been built up to 54 miles. An extremely long tramway can be built in several sections. There are tramways with a capacity up to 300 tons per hour in successful operation. Extreme length and capacity are sometimes limited from a commercial standpoint, where long railroad hauls are more economical. In the handling of material a small amount of labor is required. A tramway of 200 tons per hour can be operated by one man and a helper, with no rehandling of material. The aerial tramway is applicable for large construction jobs. There is a 220-tons-per-hour tramway for dam construction running 24 hours per day. Among tramways of special design are the tramway at Alabaster, Mich., which carries 300 tons per hour of gypsum rock from a shore bin to a lake dock 6600 ft. out; a tramway at Gerlach, Nev., which carries 100 tons per hour of gypsum rock 5¼ miles to a discharge terminal with the special feature of discharging into a bin or of forming a big stock pile outside of the station. Passenger tramways have not been built in this country to any extent on account of the opposition to this means of transportation.

THE application of aerial tramways lends itself readily to a division of two general classes—one in which the contour of the ground is so rugged as virtually to preclude the use of any other method of transportation, and the other in which the contour of the ground is such that other means of transportation may be used.

The first-mentioned class needs no advocate; it has been thoroughly demonstrated by numerous installations in the United States, in Mexico, and in South America as an economical and dependable method of transportation in mountainous regions, and was largely instrumental in developing coal and mineral deposits that otherwise were inaccessible. The view shown in Fig. 1 will convince that no other method of transportation could be used to convey the ore from the mine to the valley below.

This class of tramway application occasionally presents difficulties of an engineering nature only, such for example as dependable rope-gripping devices to negotiate unusually steep slopes; unusually long spans and the effect of high-velocity winds upon them; negotiating horizontal angles that may be necessary in the alignment of the tramway; conserving the life of the track cables and traction rope, etc.—all of which problems lend themselves readily to a satisfactory solution.

The second division of the application of aerial tramways, that in which other means of transportation may be used and must be regarded as competitive, usually presents few engineering difficulties of design, but, on the other hand, it must stand a comparison with other more orthodox methods on the grounds of economy and reliability.

The aerial tramway starts out with many advantages not

[1] American Steel and Wire Company. Mem. A.S.M.E.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

found in other methods; namely, it is independent of weather conditions; snow, sleet, floods, etc., do not interfere with its operation; in crossing streams, roads, ravines, mountains, etc., no bridging, tunneling, or trestle work is required.

Fig. 2 shows all that is necessary to provide protection to a railroad crossing.

The right-of-way is more or less easily acquired, since cable supports are few and far between, and can be so located as to be least objectionable to owners of the intervening land.

Before approaching the economic aspect of this comparison, it is well to discuss briefly the physical limitations of aerial tramways: What is the longest tramway that can be built? What

FIG. 2 GUARD SCREEN OVER RAILROAD AND HIGHWAY

is the greatest tonnage that a tramway will carry? What is the longest single span a tramway may have?

If one merely takes past performance as a guide, he may answer these questions respectively as follows:

There are at least two tramways in the United States, each 13 miles in length; one 21 miles in length in the Andes, and one in Colombia, South America, 54 miles in length; and a large number of tramways in the United States range in length from 2 to 6 miles.

At least one tramway, recently installed, was designed for a capacity of 300 tons per hour, and installations ranging from 50 to 200 tons per hour are quite numerous.

The longest single span, to the author's knowledge, is about 4500 ft. on a tramway of medium-tonnage capacity and is 6500 ft. on a tramway having a very light capacity.

Neither the length nor the capacity of a tramway is really limited since any number of tramway sections can be joined by control and transfer stations, thus giving unlimited length; also very heavy tonnages can be carried by using larger cables, larger carriers, closer spacing of carriers, and building two or more parallel tramways with common terminals; also the length of span is limited only by the height of the cable supports or by the depth of the ground depression to accommodate the deflection of the cables, provided the tension of the traction rope is kept within certain limits.

The limitations of aerial tramways as to length and capacity are therefore not physical but economical, to illustrate which one need assume only an extreme case of an occasional shipment of material over a distance of 300 miles at the rate, say, of $9 per ton of freight, and the other extreme of a constant flow of material at the rate of, say, 300 tons per hour over a distance of three miles.

In the first case the cost per ton-mile would be three cents, but in the second case the railroad expense for switching alone would be greater than the entire cost per ton when carrying this material by aerial tramway.

Here, then, is the outstanding difference between these two methods of transportation; that low rates per ton-mile are obtainable by rail for long distances, but that such low rates do not apply to short hauls of, say, two to six miles; whereas in the case of the aerial tramway, especially designed to carry usually one kind of material in bulk or in containers, such low rates are obtainable for short hauls.

In the case of the privately owned railroad the comparison would have to be made on the basis of the cost of the installation, maintenance charges, rehandling, etc.

In most cases an aerial tramway is designed to carry a constant regular flow of one kind of material taken from a central loading point in bulk or in containers, and consequently in all such cases the tramway is so designed as to handle the entire output with a minimum amount of labor for operation as well as a minimum amount of depreciation.

As an example, a recent installation, in which coal at the rate of 200 tons per hour is transported from the mine to the railroad tipple a distance of about 3400 feet, is operated by one man and a helper, and the operating costs per ton can be estimated

FIG. 3 PROFILE OF AERIAL TRAMWAY IN OPERATION AT ALABASTER, MICH.

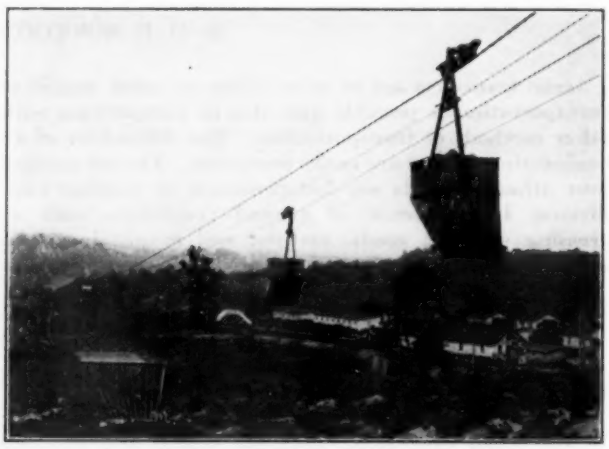

FIG. 4 CARRIER WITH FOUR-WHEEL CARRIAGE, UNDERHUNG COMPRESSION GRIP, AND END-DUMP BUCKET

easily from this. It was possible to accomplish this by means of recently developed automatic devices.

There is usually no rehandling of material where an aerial tramway is used; thus in a recent installation carrying gypsum rock at the rate of 300 tons per hour, the tramway carriers are loaded from a 1000-ton cylindrical bin and discharge their contents into a 10,000-ton bin, distributing the material over the entire width and length of the bin automatically, requiring only the occasional moving of the tripping device to various locations; in another installation even this labor has been eliminated and replaced by remote-control electrically operated trippers.

The object of this article is not to make actual comparisons of the cost of transportation by various methods, but rather to indicate, if not actually delineate, the exact field of tramway application. Such cost data are not readily obtainable for other

methods, but can be estimated easily for any given tramway project from data in possession of reputable tramway builders.

Recently aerial tramways were used in the construction of two notable dams, the Coolidge Dam near San Carlos, Ariz., and the Pardee Dam near Valley Springs, Cal.

In the first instance, sand and gravel were transported a distance of 2000 ft. at the rate of 150 tons per hour, and in the second, the same material was carried a distance of nearly four miles at the rate of 220 tons per hour. In this instance a total of about 1,400,000 tons was carried practically without interruption and with 24-hour-per-day operation, at the end of which time the equipment was still in very good condition.

The future field of application of the aerial tramway may be indicated by one installation in which cinders from a large boiler plant are loaded directly into tramway carriers which carry this waste material to a distant ravine, and another in which coal is carried from the mine direct to the coal bunkers of a locomotive-coaling station located in the coal-mining section of the country.

Mining engineers, as a rule, are conversant with aerial tramways since, as stated, this method of transportation is very often found to be indispensable in rugged, mountainous country, but it is only within very recent years that attention has been given this subject by those engaged in the planning of large construction jobs, power plants, and industrial plants.

It is with the idea of indicating some of the possibilities of tramway application that the following examples are offered:

(1) Aerial tramway at Alabaster, Mich., designed to carry crushed gypsum rock at the rate of 300 tons per hour from a shore bin to a lake dock about 6600 ft. out.

This tramway, as will be seen from the profile, Fig. 3, has eight intermediate cable supports, carried on cribs in the lake. The cylindrical shore bin is of 1000 tons capacity and is equipped with six air-operated bin gates for loading the gypsum rock into the tramway carriers, which are then automatically spaced and dispatched out on the line at exact regular intervals.

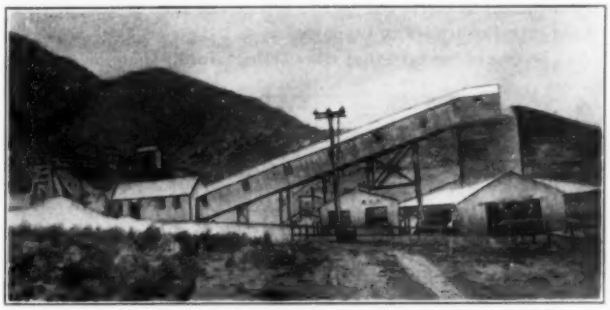

FIG. 6 LOADING TERMINAL OF AERIAL TRAMWAY AT GERLACH, NEV.

The carriers are of the type shown in Fig. 4 and are pendant from articulated four-wheel trolleys. The grips are of the underhung compression type.

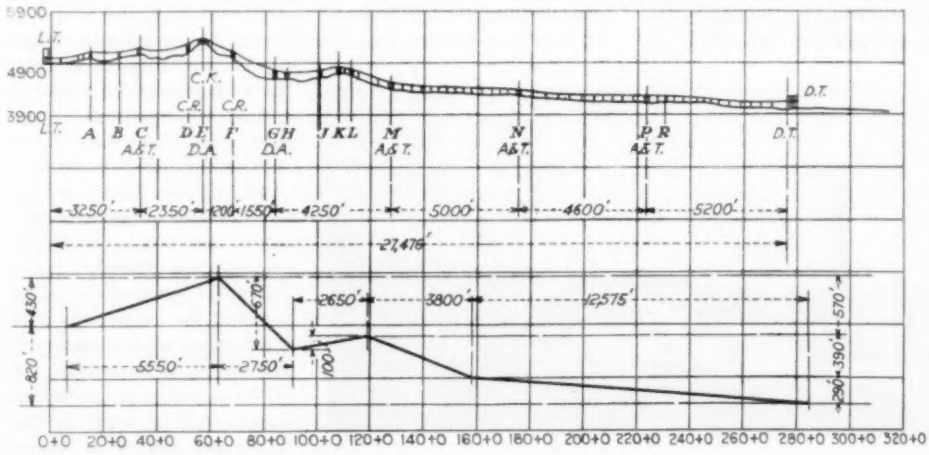

FIG. 5 PROFILE OF AERIAL TRAMWAY IN OPERATION AT GERLACH, NEV.

R	Two bent	Timber	15′ 4″	16′ 0″	19′ 0″		
D. T.	Discharge terminal	Steel	59′ about	28′ 0″	45′ 0″ about	Level	

The carriers distribute the rock over a bin on the dock that is about 300 ft. long and about 40 ft. wide; they dump their contents while in motion, and at points determined by the location of the movable automatic bucket trippers; the carriers remain gripped to the traction rope while traversing this bin, and make their turn from the loaded side to the empty return side by means of a circular rail loop placed above a sheave of the same diameter as this loop, and on the face of which the grip jaw rides, disturbing the traction rope very little.

(2) Aerial tramway at Gerlach, Nev., designed to carry gypsum rock at the rate of 100 tons per hour from quarry to plant, a distance of about 5¼ miles.

Fig. 5 shows the profile of this tramway with the summit 1250 ft. above the discharge terminal, and a net difference in elevation between the terminals of 820 feet.

Because of this difference in elevation being in favor of the loads, the tramway is practically neutral, neither requiring nor developing any power; the power developed by the loaded carriers being sufficient to pull up the empties, leaving a surplus that is just about equal to the friction of the entire system. A

motor is used however, for starting the tramway and for maintaining uniform speed.

The loading terminal arrangement is quite similar to that described in the preceding example and is shown in Fig. 6; this figure also shows the general method used in handling the material from the quarry to the tramway bin. A car dumper is shown in the background delivering the rock to a primary crusher, from which it is conveyed to the top of the bin, and from there loaded into the tramway buckets.

At the discharge terminal the carriers dump their load into a

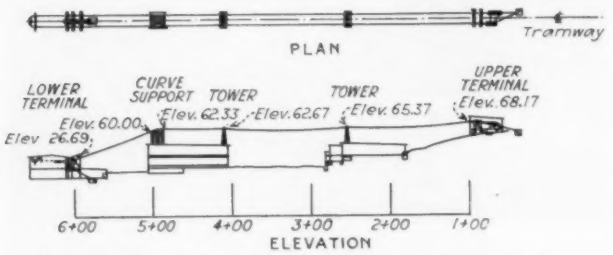

FIG. 7 PROFILE OF AERIAL TRAMWAY IN OPERATION AT SAYLESVILLE, R. I.

small central hopper that feeds the material to an open stock pile. A conveyor running under this stock pile delivers the rock to other crushers.

A revolving crane of large radius is capable of storing a large quantity of rock when quarry production is in excess of mill requirements, and stock is thus accumulated for the use of the mill when the quarry is shut down in cold weather. If it was not for this requirement, the tramway could deliver the rock direct to the crushers in the mill.

FIG. 8 PANORAMIC VIEW OF AERIAL TRAMWAY AT SAYLESVILLE, R. I.

(3) Aerial tramway at Saylesville, R. I., designed to carry rolls of cloth on trucks in an enclosed carrier over a distance of 580 ft. and at the rate of 15 trucks per hour.

This installation is described here by way of contrast to those already described, and to show the application of aerial tramways to special conditions.

Fig. 7 shows the profile of this tramway, and Fig. 8 is a panoramic view of it.

Because of the short distance between the terminals of the tramway and the small tonnage capacity requirements, the tramway was designed as a double reversible system with only two carriers permanently attached to the traction rope, so that when one carrier is at the loading terminal on one track cable, the other is at the discharge terminal on the other track cable. By reversing the direction of motion of the traction rope alternately, a load is sent out first on one cable and then on the other, with the empty returning while the load moves forward.

The panoramic view shows the congested condition of the yard between the building served by the tramway, and it is also apparent that no difficulty is experienced in going over roofs of buildings and entering the carrier into a closed building.

(4) Aerial tramway designed for carrying dynamite "dope" into various mixing buildings.

This type of tramway was developed for the use of a large corporation engaged in the manufacture of explosives, and serves to illustrate further the facility with which this system can be adopted to special and rather intricate requirements.

The primary object in the design of this type of tramway, of which quite a number are now in use, was to secure automatic operation to the greatest degree obtainable, not for labor-saving reasons, but primarily to avoid the use of men who would be in grave danger of an accidental explosion in handling the material.

How well this object was accomplished can best be judged from the following brief description:

The so-called "dope" is used in the manufacture of dynamite, and must be delivered at regular intervals to a series of mixing houses located several hundred feet apart.

This "dope" is handled in cans, each having a gross weight of 150 lb. These cans are loaded into enclosed tramway carriers, provided with hinged doors, and having a capacity of from four to six cans.

The mixing houses are located in a straight line with the loading terminal, and the problem was to connect the loading terminal with all these mixing houses by aerial tramway, and to deliver the dope to any one of the series of mixing houses without manual supervision, without stopping the operation of the tramway, and without impeding the movement of any other carrier to any of the other mixing houses.

An overhead tramway turnout rail was installed at each one of the mixing houses, as shown in the diagram, Fig. 9, and an air-operated rail switch permits the carrier to enter the turnout when closed or to proceed on its way when open.

The air valves actuating these switches are operated by bars which are located at various heights at the series of mixing houses, the one next to the loading terminal being the highest, and these bars are in turn operated by a vertically adjustable bar on the carrier called a "selector" which is set at the loading terminal at the proper height to enter any desired mixing house.

The carrier, arriving at the mixing house for which it is intended, ungrips the rope automatically, and the "selector" engages the air-valve operating lever, which closes the switch and allows the carrier to enter the turnout; it then retains sufficient momentum to engage the lever of another air valve, which opens the switch behind it, and allows the following carrier to proceed on its way; the carrier is brought to rest gently and gradually by the trolley wheels entering into a braking device that wedges the trolley wheels on the rail.

The mixing-house operator, when ready, unloads the cans and sends the empty carrier to the tail terminal, at which terminal the carrier passes around a circular rail loop, and returns on a parallel track cable to the loading terminal to be reloaded. A loaded carrier is dispatched every four minutes.

(5) Aerial tramway designed for carrying a gross load of 34 tons over a single span 2600 ft. long.

Still another special application of the aerial tramway, and one that is unique, is illustrated by Fig. 10.

The problem here was to transfer cars of sawed lumber from the sawmill on one side of the American River Canyon to the other side for storage and shipment.

The transfer car is equipped with rail of the same size and gage as the surface railroad, and the lumber cars are pushed on it after it has come to a stop against the surface rails.

As will be seen from Fig. 10, this transfer cage is supported by eight four-wheel trolleys running on four track cables, and one of the important features of the design was to insure the equalization of tension in these cables so that they may at all times all lie in the same horizontal plane. The trolleys, of course, are articulated so that the weight is equally divided among all wheels, thus insuring a moderate unit wheel load.

The importance of counterweighting the track cables, rather than anchoring them at each end, is here clearly demonstrated; not only would it have been difficult to keep the cables in the same horizontal plane, but the vertical angle of approach to the terminal rails would have been much steeper, as is shown by the fact that as the loaded cage approaches the end of its travel, about 12 ft. of cable is pulled out of the span by the counterweight.

The transfer cage makes the trip across the 2600-ft. span in somewhat less than two minutes, its maximum speed being about 1800 ft. per minute.

Special devices were developed for locking the lumber car to the transfer cage, and various automatic devices were installed for controlling the speed of this tramway.

The two terminals are at practically the same elevation, there being only about 35 ft. difference; the loaded transfer cage on leaving the terminal rails tends to run down the cable slope at great speed, which is checked and held to a maximum of 1800 ft. per minute by two 220-hp. induction motors operating in tandem and acting as brakes; on the load ascending to the discharge terminal an equal amount of power is required.

FIG. 10 CARRIER TRANSPORTING CARLOAD OF SAWED LUMBER OVER DEEP CANYON NEAR CAMINO, CAL.

On approaching either terminal a screw-type limit switch gradually reduces the speed of the motors, and the car enters the terminals slowly, and comes to a stop a short distance from the bumpers. It is then inched into position by an inching push-button.

The drive is located at the discharge terminal, but the wiring is such that the motors can be controlled from both ends; an interlocking system makes it impossible to start the motors from one terminal when the transfer car is at the other.

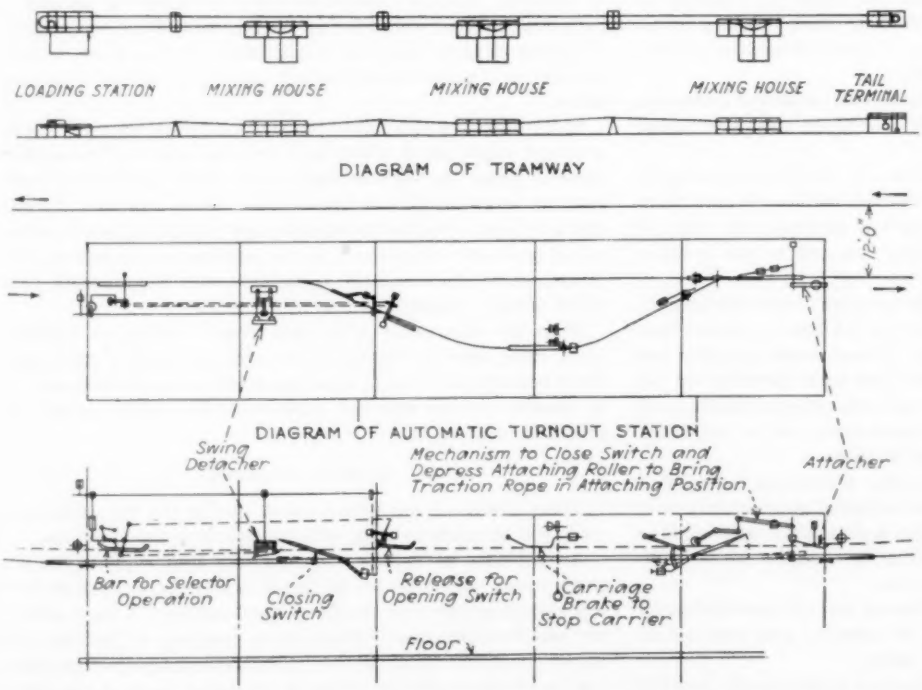

FIG. 9 DIAGRAM OF AERIAL TRAMWAY AND AUTOMATIC TURNOUT STATION IN OPERATION AT PLANTS MANUFACTURING HIGH EXPLOSIVES

PASSENGER TRAMWAYS

This field of application of the aerial tramway, which has had such a remarkably rapid and entirely successful development in European countries since the World War, has not as yet been touched in this country.

In Europe it has served to bring within reach to the general public places ideally located for winter sports, but

inaccessible by any other means of transportation; it has enabled also the average person to scale mountains previously accessible only to a few hardy individuals.

A similar problem exists in this country at various mountain resorts and national parks, but opinion is divided as to the desirability of passenger tramways at such places.

On the one hand there is the argument that these places shall be preserved in their original natural state, and that the feat of climbing a mountain shall remain a feat, an achievement, to serve as a spur in attaining physical perfection; various mountaineer clubs are presumably the most ardent opponents to the idea of making the ascent of a mountain easy and within reach of the average man.

The national park service, of course, is opposed to any idea of commercializing the natural beauties of the various scenic spots, and is particularly fearful of the hot-dog stand and the "scenery hog" that may come along with the passenger tramway.

On the other hand, we have those who argue that the foregoing reasons are not sufficiently valid to deprive the general public of at present inaccessible sites, ideally fitted for winter sports in summer time, and that it is a question also as to whether it is justifiable to create an aristocracy of the physically fit, and to deprive those not so fortunately endowed of the opportunities of viewing scenic spots from vantage points at present inaccessible to them.

It is rather difficult to believe that we shall for very long remain behind Europe in this field of transportation, and it is rather encouraging to think that the large number of such European lines installed within the last decade would tend to indicate their success and desirability.

The passenger tramway projects in Europe presumably had to cope with practically the same objections that are being brought forward in this country, and it is conceivable that in time these objections will not appear to be as serious as they seem to be at present.

The safety of this method of transportation was demonstrated by many European installations, and due credit for it should be given various European governments that have exercised strict supervision over such tramways and demanded from the builders adequate and efficient safety devices.

There are in existence several systems of passenger tramways in Europe, all of which differ mainly only in the means employed to provide adequate safety.

All of these installations are built on the double reversible system, having only one car on each track cable—the cars being spaced so that when one is at the top terminal, the other is at the bottom, and are permanently fastened to the traction rope.

The capacity of these tramways is therefore necessarily limited, but a rope-gripping device has not as yet been invented that would permit, with absolute safety, the automatic gripping and ungripping of the traction rope, and thus make possible the use of a system similar to continuous freight tramways in which many carriers could be used, the loaded ones going out on one track cable and the empties returning on the other.

It would appear at present that only a permanent fastening of the car to the traction rope could be regarded as absolutely safe, and therefore it is doubtful whether a detachable grip such as used on freight tramways could ever be designed to be sufficiently safe for passenger transportation.

The objection that the tramway would mar the natural beauty of the scenic resort where it is to be installed may also not be as serious as it may appear at first sight.

The terminals, if desired, can be located unobtrusively, and the cable span is not an ungraceful structure and hardly visible at a distance.

The cable supports are few and far between and easily can be camouflaged so as to blend in with surrounding rocks or foliage.

On the other hand, it may even be argued that the tramway terminal architecture may be made to conform to the nearby lodges or hotels, in which case, why attempt to hide it?

Several mountain resorts and some of the national parks have been confronted recently by requests for permission to build passenger tramways, and the results will be watched with considerable interest as probably marking the beginning of passenger tramway development in this country.

Discussion

JAMES F. HOWE.[2] One of the most important factors in successful tramway operation is the overhead track cable or the traction rope. Experience has shown that the type of cable known as lock coil, with external surface smooth and each wire locked in position between its adjacent wires, is the best for tramway work. This possesses the greatest number of advantages, among which should be noted smooth surface and wires interlocked so they will not permit a broken wire to strip or work out of position. The smooth external surface reduces wear to a minimum, so that long life should be secured.

Just as the proper design of a tramway is essential for the best results, the design and construction of the track cable have been improved and refined to a high degree of precision. A study of the various shapes of wire possible in locked track cable has led to the adoption of a shape that possesses good locking properties and bending properties, i.e., flexibility and good wearing properties. These wires are laid over a core consisting of one or two sublayers of key-shaped wires, and for the internal member a number of round wires. Each of these intermediate layers of wires must be constructed with the greatest precision, whether round, key, or locked wires. Variation in gage sizes of wires must be kept to the smallest possible amount.

Each wire has a niche which it must just fill if perfect cable is to be made. Shaped wires must not vary in general contour or gage limits beyond very narrow limits, because a summation of a number of plus-variations is sufficient to crowd wires, while a summation of minus-variations will produce an open or loose condition.

Many improvements have been made in locked tramway cables in recent years, all of which have been the result of exhaustive research along the various lines which study has shown would result in lengthened life of track cables. It is true that the prospective user, as well as the existing user of locked tramway cable, is in a position to have the utmost confidence in the performance of such cable when made in accordance with the scientific principles already enumerated.

Thus the uncertainty which has existed with some forms of track cable made to the less exact practice existing some years ago is entirely removed, and entirely satisfactory performance can be assured any one who uses cable made in accordance with the principles referred to.

AUTHOR'S CLOSURE

Many questions have been asked during the discussion, and reply will be made to them without repeating the questions.

Adjustability of Saddles. The saddles that support the stationary wire cables known as "track cables" on the towers have a profound influence on the life of these cables. A fixed stationary saddle under heavy wheel loads produces a "hammer and anvil" effect that results in the deformation and premature breaking up of the individual wires in the outer layer of the cable;

[2] Chief Rope Engineer, American Steel & Wire Company, Worcester, Mass. Mem. A.S.M.E.

also, a saddle having a short radius of curvature introduces excessive bending stresses which tend to destroy the cable prematurely.

In a modern, properly designed tramway, therefore, the saddles are made rotatable and rock in their journals with any change in the slope of the cable, thus presenting a yielding surface to the trolley wheels; also these saddles are usually made with a radius of curvature of from 15 to 25 ft., depending on the size of the cable, and of sufficient length such as to prevent the cable from bending over the ends of the saddle when the slope of the cable on both sides of it is a maximum.

Replacement of Worn Cables. Tramway track cables are made up as a single strand, hence they cannot be spliced in the same way as an ordinary wire rope, but must be joined by means of mechanical couplings.

To each end of the cable a half of a coupling is attached having a conical basket into which the wires are spread and held in place by semicircular steel wedges and fillers, thus forming a solid steel cone. One half of the coupling has a right-hand thread while the other is threaded left-hand, and the two are joined by a right-and-left-hand connecting plug.

The track cables do not wear uniformly all along the line of the tramway, but usually wear out first at the supports.

Usually a short piece of about 100 ft. is coupled in to replace a worn section, and the method of coupling varies with local conditions. In some cases the tension can be slacked off, the cable let down on the ground, and the coupling made up, while in other cases it may become necessary to affix clamps to places beyond the worn section, and by pulling these clamps together by means of powerful wire-rope block and tackle produce slack at the coupling place and make the repairs from an aerial platform suspended from the cable.

It is seldom necessary to replace the entire cable, but worn-out or defective sections can be replaced by short lengths as required. The introduction of couplings, when these are properly put on, seems not to affect the life of the cables.

Inspection of Cables. Track cables should be periodically inspected. This is usually done by the inspector standing on a carrier which brings his eyes at about the elevation of the cables; with the tramway running at reduced speed, the cables can be thoroughly inspected.

It also is possible usually to make these observations by climbing the towers and looking over the cables with the aid of a powerful field glass.

Maximum Length of Span. The deflection of a counterweighted cable span varies as the square of the span and also is proportional to the number of carriers upon it, and therefore a long span requires either a deep intervening ravine or very high supporting towers, so that the limitations are physical and not theoretical.

The span being counterweighted, the cable tension remains independent of the length of the span and of the number of carriers upon it.

Corrosion Prevention. The track cables and traction rope of a tramway must be protected from corrosion. In the case of the track cables, this is done by a special carrier containing a suitable quantity of lubricant, which is sent out periodically to make circuit of the tramway. A cam on one of the trolley wheels actuating a valve allows a small quantity of lubricant to be deposited on the track cable with each revolution of this wheel, which also spreads it along the cable. The traction rope is oiled by running it over a sheave immersed in oil in a stationary tank located at one of the tramway terminals.

Cost per Mile. The cost per mile of an aerial tramway varies with the following major factors:

(1) The contour of the ground
(2) The length
(3) The capacity in tons per hour
(4) The weight of the material per cubic foot
(5) Facilities for distributing and erecting
(6) Local costs of labor
(7) Material of structures, i.e., steel or timber.

Since the combination of these factors forms an endless variety and they seldom repeat themselves, it is impossible to state with any degree of certainty just what is the cost per ton-mile.

MH-52-5

Designing for Safety in Materials Handling

By R. H. HUCKE,[1] SCHENECTADY, N. Y.

The author covers the special handling of large cases for shipment. The equipment designed to meet the operating conditions is described, and also the features of safety and speed in handling materials. Every conveyor before installation must pass the inspection of the works engineer, and after installation the system is checked over to see that proper guards and switches are supplied.

UP TO a few years ago very little attention was paid to the materials-handling problem. However, since the war, which killed a large number of men who would naturally come as laborers, and also owing to restricted immigration, materials handling has been getting more and more attention from industrial leaders through the advent of mass production in manufacturing. This company, like all other manufacturers, has been installing equipment gradually for handling materials, both raw and in the process of manufacture.

In the past few years much activity has been centered around the manufacture of refrigerators, which, because of the large production and size and weight of the product, presented an excellent opportunity for mechanical handling. The magnitude of this job can be visualized better by giving a few statistics on the raw material required to keep the production up to schedule.

Approximately nine carloads of insulating materials are handled from the cars to storage or to assembly lines per week. To handle this amount of material, which is only a small part of what goes to make up the refrigerator box, would require a crew of fifteen to twenty men and a fleet of trucks. With a conveyor system four to six men handle all of the material, and this also eliminates congestion. The manufacture of the refrigerator box requires a large tonnage of steel which is fabricated into shape, after which it is prepared for painting and enameling. As soon as it is finished, ready for painting, it is suspended from an overhead chain which carries it through the several finishing operations, through the ovens, and directly to the assembly floor. This chain conveyor is approximately 5000 ft. in length, and this has permitted reducing the amount of material in process to a point where the manufacturing and assembling can be carried on in a floor space considered entirely inadequate with any other means of handling the parts.

The assembly is organized in a continuous straight line on a moving apron conveyor to a point where it is ready for shipping. At this point another conveyor takes the packing cases from the carpenter shop to the assembly line, where the units are completed and made ready for shipment. At this point the boxes are dropped into the packing cases and carried to the shipping platform by means of a conveyor which is described later. Bearing in mind that these units vary in weight from 400 to 1100 lb. each, this conveyor has many novel features.

When this company entered the refrigerator field with an all-steel cabinet, safety was an important factor. In the design the cabinet featured the art of preserving food safely with good appearance. With the production of these cabinets at the Schenectady Works, the safety thought was continued. Safety to the employees, and also in the handling of the cabinets, as in the beginning of their manufacture, still prevails today.

During the beginning of the refrigerator-cabinet production, conveyors and other mechanical-handling equipment played a small part in the picture as compared with their application to the present layout. There are several reasons for these changes from simple to elaborate handling systems. In the beginning the output of cabinets was small and did not warrant the expenditure of large sums of money for handling equipment. As the production on these cabinets increased, and with the addition of three larger-size cabinets, it became necessary to improve the handling facilities of the department. This was done without limiting any expense in making the new conveyor systems as efficient and safe as possible.

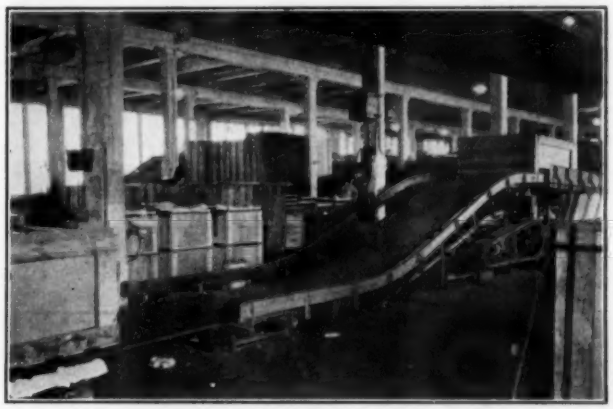

FIG. 1 LOOKING FROM THE END OF THE TWO-DOOR CABINET-ASSEMBLY LINE TOWARD THE POWER INCLINE APRON-TYPE CONVEYOR

A description of the new shipping-conveyor system for handling the refrigerator cabinets is interesting because of its safety features. The question that may be asked is: What are the duties of this new conveyor system, and how are they accomplished? The duties are to convey the cabinets from two similar cabinet-assembly lines on the second floor of the building down to the shipping platform and then to the freight car. The one line conveys large cabinets; the other, small cabinets.

These cabinet-assembly lines on the second floor are in parallel, approximately 40 ft. apart, and run longitudinally with relation to the building. One is used for the assembly of the one-door cabinets; the other, for the two-door cabinets. The shipping platform is located along the east side of the building and is long enough to accommodate six freight cars.

The operation of the new shipping-conveyor system begins with receiving the two-door cabinets in their shipping crates, backs down, and feet at right angles to direction of travel. They are conveyed from their assembly line in this position by means of a power-driven conveyor of the inclined apron type to a section of roller gravity conveyor. (See Fig. 1.) These cabinets, while still on the roller gravity conveyor, make a 90-deg. turn and then head across the second floor to an opening in the wall of the building. This section of roller gravity conveyor is not at right-angles with relation to the one-door cabinet assembly line.

The one-door cabinets are received from their assembly line in shipping crates, with backs down, and feet pointing in direction of

travel. In this position they are conveyed to the same section of roller gravity conveyor as the two-door cabinets by means of an apron-type conveyor. An interesting feature of this part of the system is the simple automatic arrangement for the transfer from the apron-type to the roller-type conveyor at right angles, and at the same time changing the direction of travel of the one-door cabinets from a longitudinal to a transverse position on the section of roller gravity conveyor. This is accomplished by a series of power rollers, set in such a manner as to control accurately the direction of the one-door cabinet until released to the roller gravity conveyor. The one-door and two-door cabinets

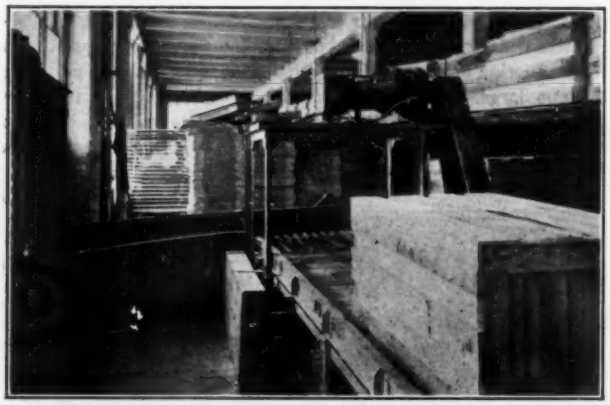

FIG. 2 TRANSFER POINT FROM ONE-DOOR CABINET-ASSEMBLY LINE TO ROLLER GRAVITY SECTION OF CONVEYOR
(Wall opening to the left.)

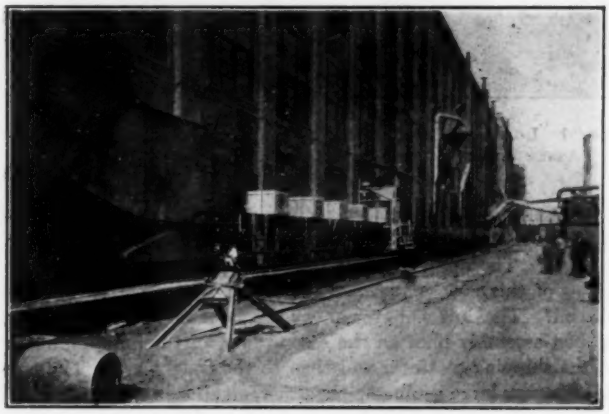

FIG. 3 GENERAL VIEW OF THE SHIPPING PLATFORM

are now on the same conveyor, with their feet at right angles to the direction of travel.

All cabinets, after passing through the wall opening on the roller gravity conveyor, ride a 90-deg. gravity roller curve which delivers them to an inclined power apron conveyor. (See Fig. 2.) This conveyor is in line with the shipping platform. The cabinets are carried down the incline on the apron conveyor to a power roller flight conveyor, which extends the full length of the shipping platform. (See Fig. 3.) This type of conveyor was employed to furnish ample storage of cabinets while the freight cars are being shifted. This is essential, as production must not be interrupted while the loaded cars are being removed from the siding and replaced by empties.

The frame structure of the power roller chain conveyor is so constructed as to carry rails on which two power-propelled semi-automatic tilting devices, called unloaders, run. (See Fig. 4.) The purpose of the unloader is to remove the cabinets from the power roller chain conveyor and deliver them to the freight-car floor in an upright position, with feet down. (See Fig. 5.) Each unloader is equipped with an individual motor drive, which propels it along the power roller chain conveyor through a rack and pinion. (See Fig. 6.) This drive is controlled manually so as to permit the operator to move the unloader to the freight-car door, no matter where the car may be stationed along the siding.

The unloader consists of two distinct operating parts—the transfer arm, or kick-off, and the tilting mechanism. (See Fig. 6.) These two operating parts are equipped with separate motors and worm-gear reduction units. (See Fig. 7.)

As each size cabinet is of a different width, and all cabinets must be diverted from the power roller chain conveyor approxi-

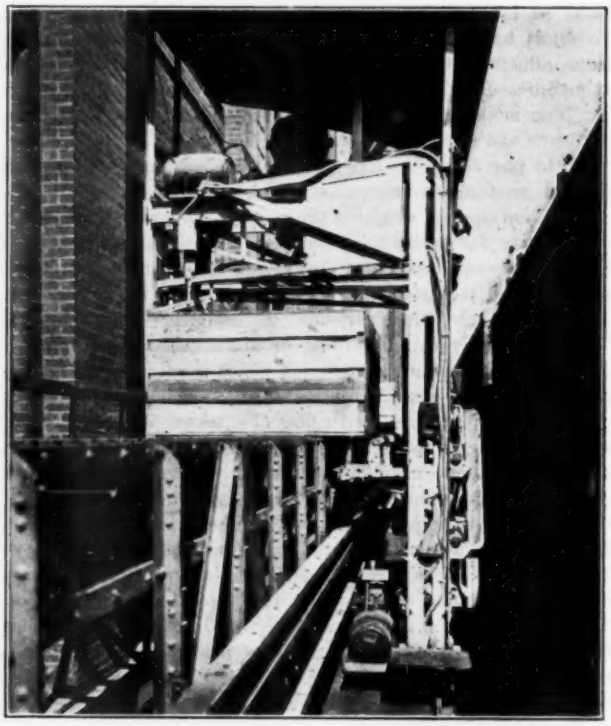

FIG. 4 SIDE VIEW SHOWS CRATE PASSING THROUGH UNLOADER

mately at the center of the unloader, a special electric switch was designed, called the selector. This selector consists of several contacts, one for each size of cabinet. Each of these contacts is connected to a limit switch, which is mounted on the unloader frame and set to start the transfer arm at the proper time for each size of cabinet.

The arm on the unloader is used to transfer the cabinet from the power roller chain conveyor to the tilting mechanism. This is accomplished in the following manner: The cabinet, still on the power roller chain conveyor with its feet pointing toward the freight car, enters the unloader and engages the transfer arm. This automatically sets the contact, or selects the limit switch which is to divert the case. When the case has thus set the selector and depressed the proper limit switch, the transfer arm motor starts and, in turn, through a crank and lever movement, diverts the cabinet from the power roller chain conveyor to the tilting mechanism.

When the transfer arm has reached the end of its outward stroke, it closes a limit switch, which starts the motor oper

ating the tilting mechanism table on its downward movement. This movement is through a worm reducer, pinion and gear segments, which causes the table to move through an arc of approximately 90 deg. The cabinet is lowered to the freight-car floor on its feet and is manually removed from the tilting mechanism table and trucked to its position in the car.

For safety, the tilting mechanism does not return to its loading position automatically, but by the operator pushing a starting button. A complete set of emergency buttons is also provided so that the unloader can be controlled through them temporarily, in the event of failure of a limit switch. Lights are mounted on the loading-machine frame for illumination at night.

When it is desired to operate the two unloaders simultaneously, the cabinets may be "by-passed" through one unloader to the

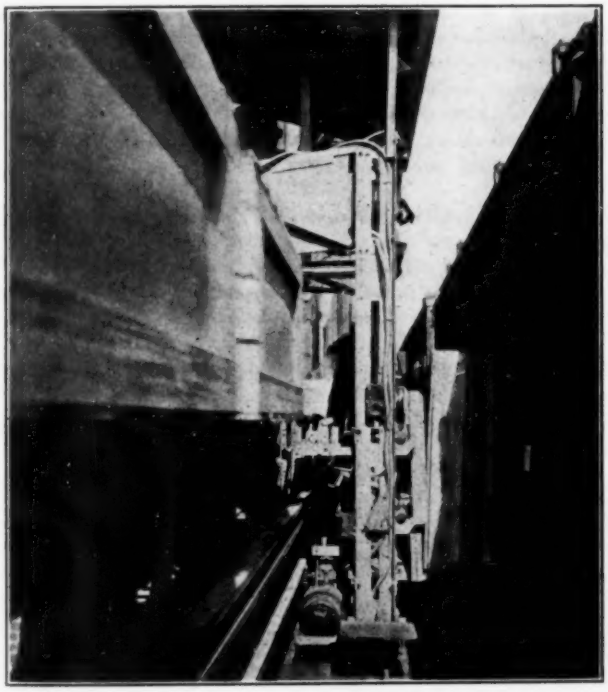

FIG. 5 CABINET DELIVERED TO FREIGHT-CAR FLOOR

other by the operator throwing a switch. This is usually done when more than 50 cabinets per hour are being loaded.

The unloaders are the main feature of the entire conveyor system because of the efficient and almost human manner in which they accomplish their task. This was made possible by a series of specially designed selectors, limit switches, conductor rails, contacts, and motor controls, in combination with ingeniously applied mechanical movements.

With this new conveyor system, a carload—consisting of 51 single-door cabinets, weighing approximately 400 lb. each—was delivered to the freight car in 35 minutes. The only help required was two men in the freight car. This is about half the time and half the number of men formerly required to handle the same number of cabinets. The two-door cabinets, weighing 800 and 1100 lb., respectively, are handled with ease by the new conveyor system. Formerly these cabinets were placed on a truck and lowered to the first floor by a platform elevator, and then trucked to the freight car. This method was a laborious one and required the services of an additional crew of men.

In commenting upon this new conveyor system, it may be said that it has helped to increase and hasten the shipping facilities of the department. The crated cabinets are handled from their assembly lines to the freight cars with the utmost safety. Safety, also, has been realized by reducing to a minimum the human element involved in operating the system. This we

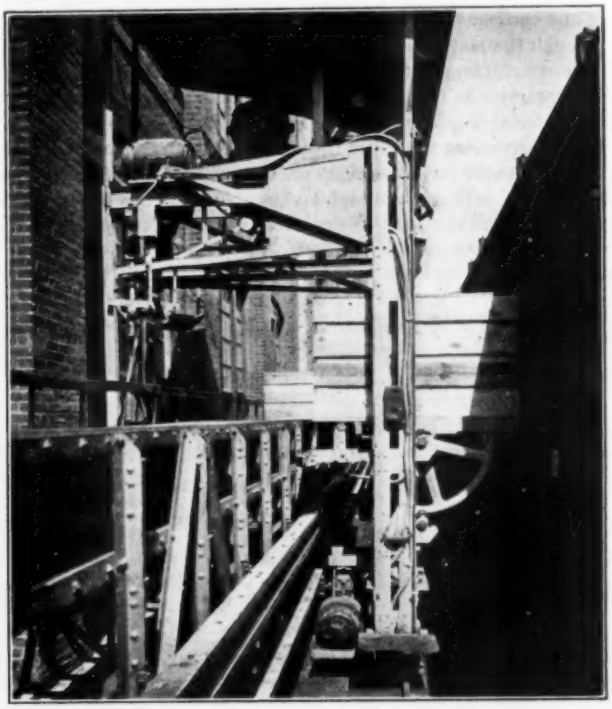

FIG. 6 SHOWING CABINET TRANSFERRED TO THE TILTING MECHANISM

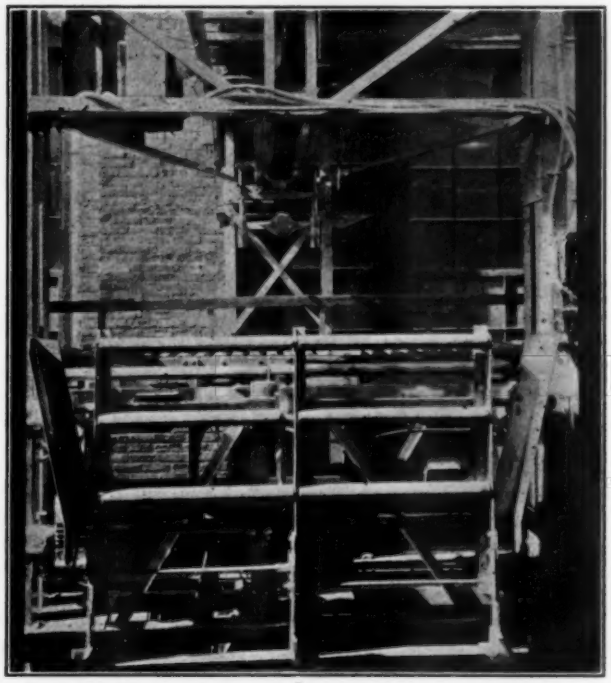

FIG. 7 VIEW OF UNLOADER FROM FREIGHT-CAR DOOR

accomplished in large measure by applying the electric equipment that controls the movement of this conveyor system.

Another feature that should be mentioned is the fact that all the conveyors in the system are properly guarded to insure safety to the employees.

This conveyor system is one of many in the Schenectady Works of the company that are doing their work efficiently and safely through the help of electricity.

In concluding, it may be stated that the following procedure is in practice at the Schenectady Works in the selection and use of material-handling equipment: To help insure safety, all layouts involving the use of conveyors are submitted to the works safety engineer for inspection. A thorough check, from a safety standpoint, is thus given each layout. No conveyor is permitted to be installed until the works safety engineer is satisfied that it will be safe. After the conveyors are installed, another inspection is given them to further the cause of safety before they are put into final operation. No expense is spared in the use of guards and safety switches.

Only designated employees are permitted to operate the conveyors, and they are instructed at all times to play safe in their work. Accidents result in a loss of time and money to both the injured employee and the company because the amount of compensation received cannot equal the worker's regular earnings, and the cost of compensation represents an expense that must be added to the business. The work of properly promoting the interests of safety is important, and the company realizes that it pays to give considerable attention to this item.

Recent Developments in Material Handling at the Western Electric Company's Merchandise Buildings at Kearny, N. J.

By C. K. PEVEAR,[1] KEARNY, N. J.

A description is given of the Western Electric Company's merchandise buildings at Kearny, N. J., their purpose, and the methods used in material handling in these buildings. A thorough study was made of the purpose of these buildings, the type of the material to be handled, and the possible future changes that might be made in the amount of work to be done and the dimension of units handled. Then the warehouse activities were laid out, and a building was designed to enclose them. Approaching the problem in this manner provided unusual design opportunities not generally met, as in most cases equipment has to be fitted into an existing building.

THE Western Electric Company at its three plants (Hawthorne, Kearny, and Point Breeze) manufactures telephone apparatus and delivers it to the Merchandise Department's three warehouses at the same places. The Merchandise Department in turn receives, packs, stores, and delivers this material to the 32 distributing houses. These distributing houses receive the material in wholesale lots, and then select, ship, and deliver the apparatus to the telephone companies in retail amounts.

At the present time the Kearny Manufacturing Department is called upon to produce approximately 20,000 different items. Some of these items are piece parts, which, when assembled, make up the larger units. The Merchandise Department is required to stock approximately 9000 items. These items vary in weight from less than an ounce to a ton; they vary in size from a piece as small as a pinhead to units 10 ft. long, 8 ft. high, and 6 ft. wide.

The Kearny Merchandise Department may receive an order for one of these piece parts or the order may call for a new telephone exchange. One piece part would probably be for repair of some old piece of equipment that is discontinued and therefore is not stocked, and it would be ordered from the Manufacturing Department; while the order for the new exchange would be broken down into the parts that are stocked ordinarily and the parts that it is necessary to manufacture. This order for an exchange has to be almost entirely accumulated in the warehouse before shipment can be started to the building where the exchange is to be installed. This accumulating period may be from three to six months.

The value of the material stored is approximately $1 a pound, and often there is $10,000,000 worth of stock and of partially assembled switchboard jobs on hand in the Kearny buildings.

Description of Buildings

Although they were not considered first when the layout was being made, a general description of the buildings will be necessary so that the references to floors, balconies, auto courts, etc., will be understood. (Figs. 1, 2, and 3.)

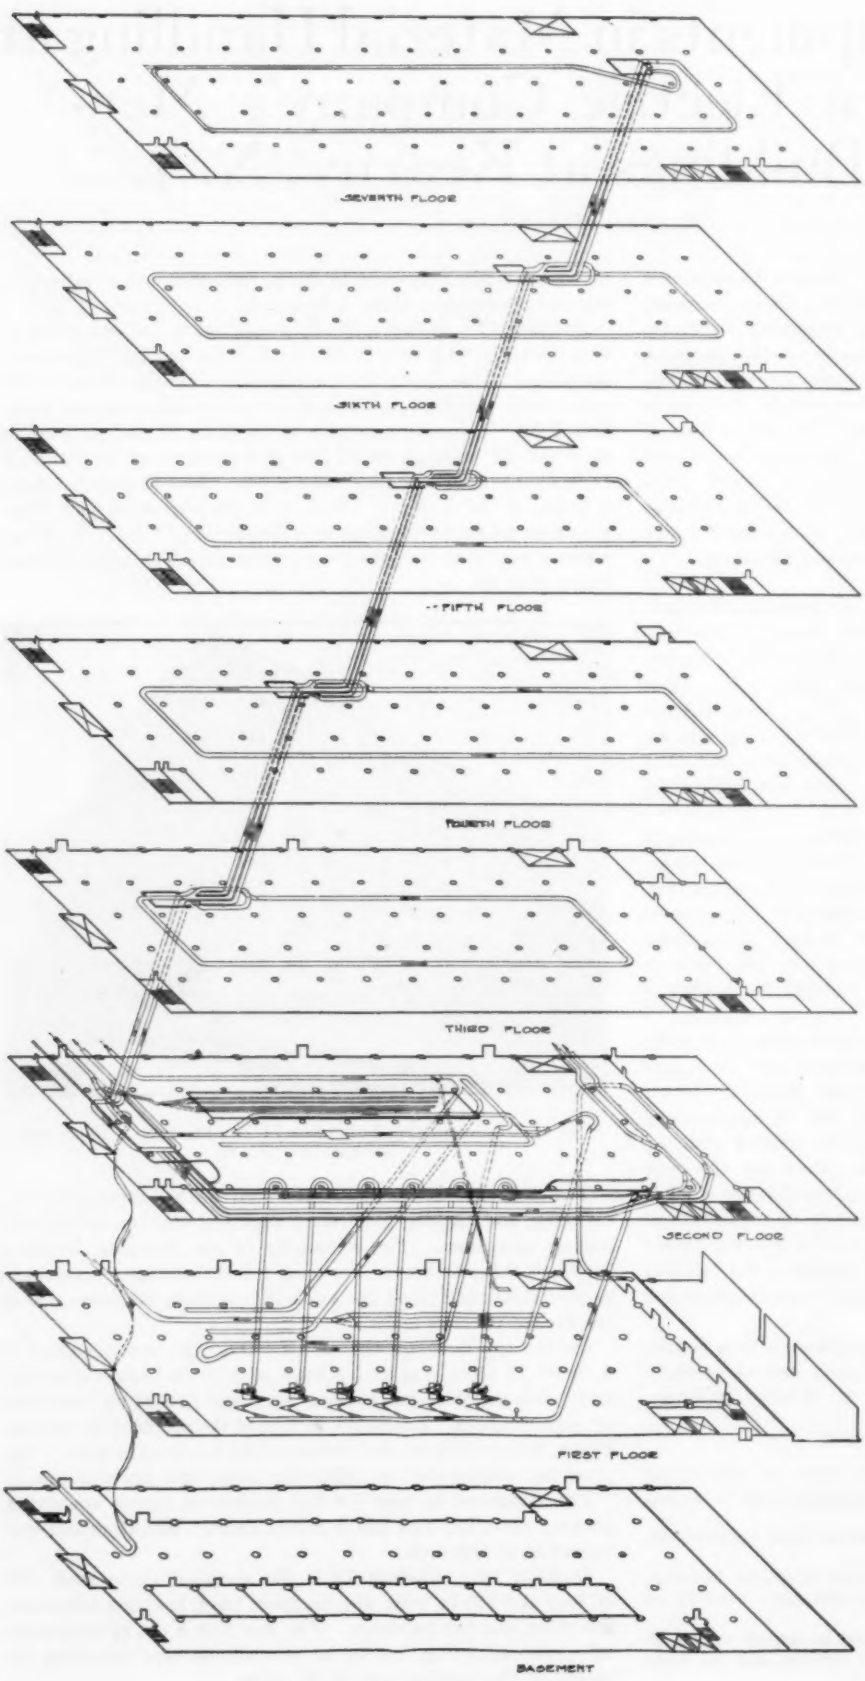
Building 71. Building 71 is a multistory building, 300 ft. long by 100 ft. wide with 20-ft. bays, containing eight floors and a basement. The second floor is really a mezzanine floor; it has many large openings and is actually a vertical extension of the first floor. The ceiling heights of Building 71 are so designed as to get the greatest use of the cubic contents of the building; 11 ft. floor to floor with floor slabs of 9 in., which makes the ceiling a height of 10 ft. 3 in. Thus, with the sprinklers and 18-in. clearance under them there is sufficient height for 8-ft. piling, which height is all that the average man should be asked to stack boxes unaided.

Fig. 1 Merchandise Buildings 71 and 72, Taken From the Southeast Corner

The first and second floors are used for receiving, packing, checking, and packing material storage and also the sealing and nailing operations. The remainder of the floors in Building 71, from three to seven, are used for the storage of standard packed stock, and along the south side of these floors are placed the broken-package racks.

On the top floor are the offices. Over the center section is a turret 13 bays long and 3 bays wide, with trusses spanning 60 ft., leaving this area without posts and lighted on four sides by high windows. In the low section of the top floor the private offices, toilets, lockers, and women's rest room are located. The plastered trusses act as baffles for noise and prevent echoes.

The basement is used for the storage of excess apparatus, packing material, and has a record vault. Elevators and conveyors serve this area.



Building 72. Building 72 is the so-called crane shed, 300 ft. long and 100 ft. wide, also on 20-ft. bays, having a basement, first floor, and two balconies. The first floor is cut up lengthwise by a railroad siding, leaving on one side an area extending the length of the building and 20 ft. wide.

---

[1] Assistant Distribution Engineer, Telephone Sales Department, Western Electric Company.

Presented at the Third National Materials Handling Meeting, Chicago, Ill., March 5 to 7, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The first balcony is on the same level as the second floor of Building 71 and extends from the wall of Building 71 to within 3 ft. of the railroad track. The second balcony is on the same level as the third floor of Building 71, extending from the wall of Building 71 over the railroad track some 8 ft., leaving a long slot between the second balcony's edge and the building wall approximately 12 ft. wide. This balcony is also cut off on the west end so that the second balcony and railroad track are exposed.

The first floor is used primarily for shipping, also for some carload receiving of apparatus and excelsior. The first balcony is used for the accumulation of small miscellaneous items on switchboard jobs and the manufacturing of plywood boxes and panels. The second balcony is used for the accumulation of bulky items such as switchboard jobs, as well as switchboard, power, and lead-covered cable, and has a 500-lb. floor load with a piling height under the crane of 35 ft.

The basement is used for the storage of excess of lead-covered cable, iron work, and slow-moving material. Elevators and crane serve this area.

Truck Courts. At the east end of Buildings 71 and 72 are automobile truck courts extending the width of the buildings, 100 ft. They are entered by three large Kinear doors, two approximately 40 ft. wide and one 20 ft., each court having a capacity of 10 trucks. These doors are electrically controlled from a shipping office, which is located between the two courts on the second floor level and has windows looking out on both and a periscope toward the front; with these windows a clerk can control the placing of the auto trucks and keep the Kinear doors closed in inclement weather.

Crane. The first floor and balconies in Building 72 do not extend to the east wall but are 40 ft. back, so that the crane, which extends the length of the building, is able to place incoming material on the second balcony, one end of the first balcony, on several places on the first floor, and to remove or place material on all of the trucks in the court at the east end. The crane also can place bulky boxes alongside all the cars and can reach down to the first floor and

FIG. 2 (*Left*) ISOMETRIC DRAWING SHOWING CONVEYOR LAYOUT IN BUILDING 71

basement through a hatchway and trapdoor. It can land material on the fourth and fifth floors of Building 71 on the east end as there are small hanging balconies extending out from the wall of 71 on these floors.

There is a sidetrack along the north side of the crane shed building, and the doors in the north wall of this building at the first-floor level are placed so that six cars can be spotted on this track. Thus, the crane can service all the cars on the outside track, as well as those on the inside.

Bay Numbering. All the area in both buildings, with the exception of that occupied by offices, is definitely numbered. On each floor in Building 71 there are two lengthwise aisles which are the streets that the bays face on; the bay numbers have four digits; the first showing the floor (the letter "B" showing the basement), the second digit showing the row of bay numbers starting from the south, the third and fourth digits showing the bay number starting from the east with the number 11; thus 3211 is the third floor, second row, and first bay. The scheme of bay numbering is carried out on the areas of building 72, starting with row 5, so that the number 2514 is the first balcony, or second floor, first row, and fourth bay.

Painted on the inside wall of the crane, Building 72, there is a 2-ft. wide black stripe, about 35 ft. from the second balcony floor. On this stripe are painted the bay numbers, two numbers to each building bay. (Fig. 4.)

On the under side of the crane girders are painted in white the row numbers on 10-ft. centers. Thus, if the area assigned to a box is 832, the crane moves out to row 8 and down to bay 32, and as the row and bay limits are defined by lines on crane girder and wall, the operator does not have to see marks on the floor, but keeps his cables within these limits and deposits his box in the assigned area very easily.

Heating and Ventilation. The building is entirely heated by unit-type heaters, controlled by thermostats, and during the summer the apparatus is used for cooling and ventilation. On the third to the seventh floors are placed large openings, 5 by 6 ft., three on each floor, between the crane building and the multistory building. These are guarded by heavy screening as well as firedoors, and when opened in the summer time have a remarkable cooling effect upon the temperature of these floors.

Handling of Material

At Hawthorne and at Kearny the buildings are so separated from the manufacturing buildings that automobile trucking is required. It may seem peculiar at a first glance that the buildings are not attached so that the delivery of this vast quantity of material can be made by conveyors or electric trucks. However, because of the tremendous quantities and number of different articles made, manufacturing operations are necessarily scattered. In each building material is brought down to the first floor and loaded on auto trucks at different loading platforms. When these auto trucks are unloaded and received by the Merchandise Department, the material is divided into two classes—large bulky items and small items.

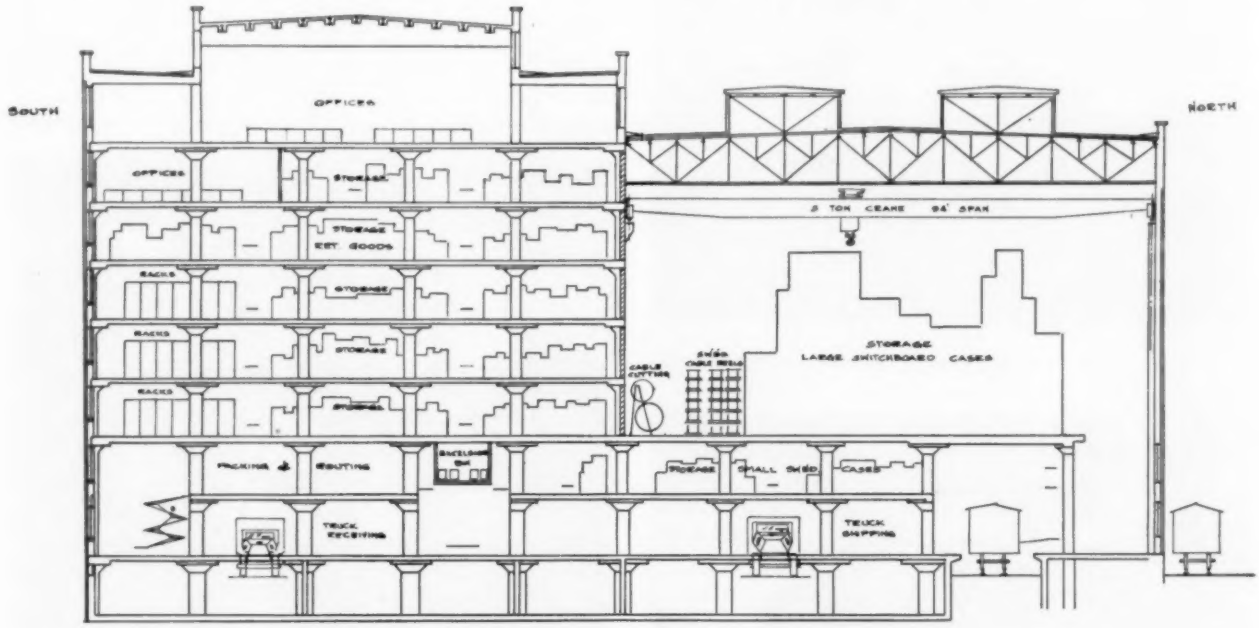


FIG. 3 CROSS-SECTION SHOWING ELEVATIONS OF BUILDINGS 71 AND 72

Bulky Material. Bulky items are brought into the warehouse on the east end of the first floor of the multistory building. These are, for the most part, on platforms and are deposited momentarily on the floor and very close to the doors leading from the automobile court. There is installed a tramrail hung from the ceiling, which has a floor-controlled electric hoist and the carrier pushed by hand. The larger and heavier material is handled entirely from the platforms to the storage conveyor by this tramrail, the operation being as follows:

A platform with its load is deposited approximately under the center of a branch of the tramrail. A special tackle with a very large adjustment is hooked on the apparatus, which is hoisted and pushed along the rail through switches, so that it is suspended over either of the three storage conveyors. The bottom of a box is sent down from the floor above and is placed on a pallet conveyor. Then the apparatus is lowered to this box bottom, which becomes a skid. A considerable amount of this apparatus is of such size and rigidity that it can be lowered into a completed box by this carrier, and then packing details are wedged and nailed in place so that the apparatus becomes very solidly packed. (Fig. 5.)

The pallet-type power conveyor starts at floor level and ascends

at a gentle slope until it is approximately 3 ft. high. There, a box or loaded skid runs down the gravity storage lines, which extend some 100 ft. There are three conveyor lines of this type running parallel with each other and very close together, so that there is considerable storage before the actual packing and nailing conveyor starts. There is a three-way switch connecting the three storage lines with the single packing line. The packing line consists of a three-rail roller conveyor, 11 in. off the floor, one side of which is a live roller conveyor with snub rolls underneath one side, bringing the moving belt to bear

FIG. 4 CRANE AREA SHOWING BAY NUMBERING SYSTEM

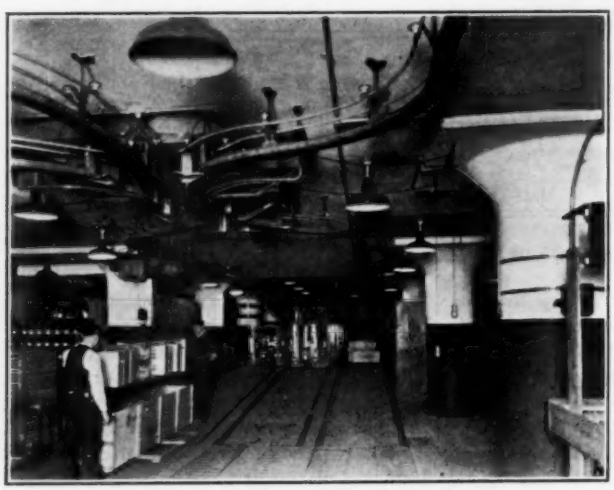

FIG. 5 BULKY ITEM HANDLING TO PACKING STORAGE LINES

on the under side of the upper rolls. The speed of this conveyor is approximately 8 ft. per min., and the packers, who are really box assemblers, can do their work as the apparatus and skid move by them. The sides, tops, and ends, in a majority of cases, are plywood panels and are delivered to the packers on gravity conveyors running down from the second floor through a large opening approximately 120 ft. long by 20 ft. wide. This opening enables the box suppliers working on the second floor, where the packing material is stored, to see the storage lines below and be able to send down on the conveyors the proper materials to make up the boxes in their proper sequence. (Fig. 6.)

At the end of this general packing line the conveyor turns at right-angles to the marking and scale section, and then goes through a large opening in the wall into the so-called crane shed, Building 72, where the majority of this large material is stored. Over this conveyor is a hatchway or opening in the balconies above, so that the crane can reach down through these balconies and remove the boxes from the conveyor.

When this large material is received from the Manufacturing Department, it has attached to it the receiving papers, which give a description of the material and the order number on which it applies. A copy of this ticket is removed and sent by means of a pneumatic tube to the recording department, where the receipt of this material is entered on an accumulation sheet, one of which is started for each switchboard job. This job may be one which is "shipping," that is, the first shipment has been made and all subsequent material is shipped at once. The receiving ticket is so marked and a stencil is cut, then both are sent by pneumatic tube to the marker's position and held there until the box comes by, when it is addressed according to the shipping information. If, however, the job is being accumulated, then the clerk gives it a number which designates the area assigned to the accumulation of this job and it is sent by pneumatic tube

FIG. 6 GENERAL PACKING CONVEYOR

to the marker's position. The marker places this assigned area number on the top of the box, and this, in turn, informs the crane operator exactly where the box is to be placed.

The crane requires a word of explanation. The cab position is unusual, as it is mounted directly above the hook and, in fact, is a part of the hook, as the top of the shank above the ball race is a large plate with holes in it and becomes the bottom of the cab. The operator sits down and his feet rest on this plate, so that he can swing the hook and load by pushing the plate and at the same time look through the slots or over the edge of the floor and see the position of his load.

The control of the crane is entirely within this cab and is accomplished by pilot circuits through relays. The hoisting speed is 150 ft. per minute, which is necessary because a lift of 60 ft. must sometimes be made before the crane can travel in the other directions.

It was necessary for the operator of this crane to be on the hook, for he must unfasten the tackle from the box and also attach it when loading. Floor men could not climb to the tops of these piles as some are 35 ft. high, and many ladders, aisles, and men would be required, as the crane very seldom has two boxes going to the same bay in succession.

Small Material. The smaller material is sent over from the Manufacturing Department in containers which are approximately 24 in. long, 16½ in. wide, and 6 in. deep. These containers are usually placed on platforms or on shelf trucks. When they arrive in the Merchandise Building, they go to the checking department on the first floor, which not only checks the receiving ticket for quantity and kind, but also sorts the material out into two classes—one to be packed and sent to stock, and the other to be placed in racks as non-stock items awaiting shipping instructions. When these instructions are received, the material is sent by means of dumbwaiters to the second floor, and the miscellaneous checker packs them for shipment. The first class is then packed on the standard packing line. The checking operation, as described, especially on stock items, is really a part

FIG. 7 STANDARD PACKING LINE SHOWING EMPTY BOX LINE HUNG FROM CEILING

of the packing operation, inasmuch as it is checked and packed at the same time. (Fig. 7.)

The foreman of the standard packing line reviews the material to be packed every hour and makes out a schedule calling for the number, size, and order of the boxes he requires. The empty boxes on this schedule are sent from the second floor to the first floor on a conveyor, which runs along the ceiling of the first floor for a considerable distance, then turns and continues at a convenient height for the packing operations. This conveyor provides enough room for the storage of a complete schedule of empty boxes.

The packing line is rather unusual in design. At first glance, it appears to be a regular flat roller conveyor, but underneath its length runs a belt supported on snub rollers in a frame. When the motor is started by means of pushbuttons along the side of the conveyor, the belt moves. At the same time, a second motor is put into operation; it elevates the frame and snub rollers, until the belt is in contact with the underside of the conveyor rollers, thus making the line a live roller conveyor. When the belt is raised to the required height, the second motor automatically shuts off. When the stop button is pressed, the belt stops and the second motor is started, which

FIG. 8 DISPATCHER'S POSITION

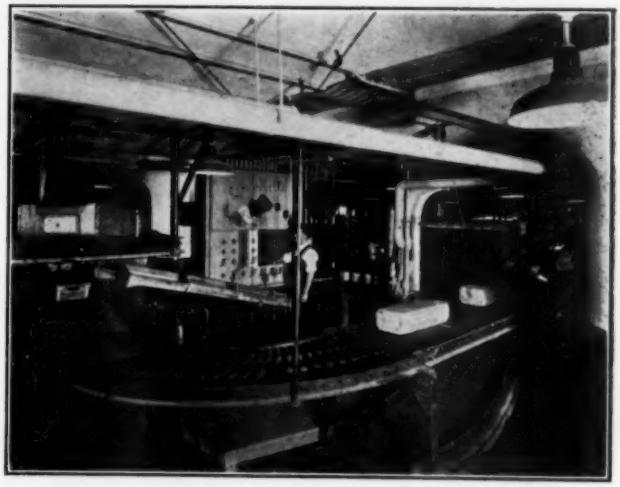

FIG. 9 SIGNAL AND CONTROL PANEL

lowers the frame and snub rollers and then automatically shuts off.

The conveyor is used in the following manner: The skids loaded with containers of the same kind of apparatus are placed alongside of the conveyor. The motor is started, bringing the

empty boxes along the conveyor opposite the skids, then it is shut off. The packers spread the boxes and the containers alternately on the conveyor. This they are able to do easily, as the rollers are free from the belt. Then they pack the boxes, the belt is started up, and the empty containers and full boxes go down the line to the marker and scale section, where the empty

FIG. 10 BOTTOM OF CONTAINER

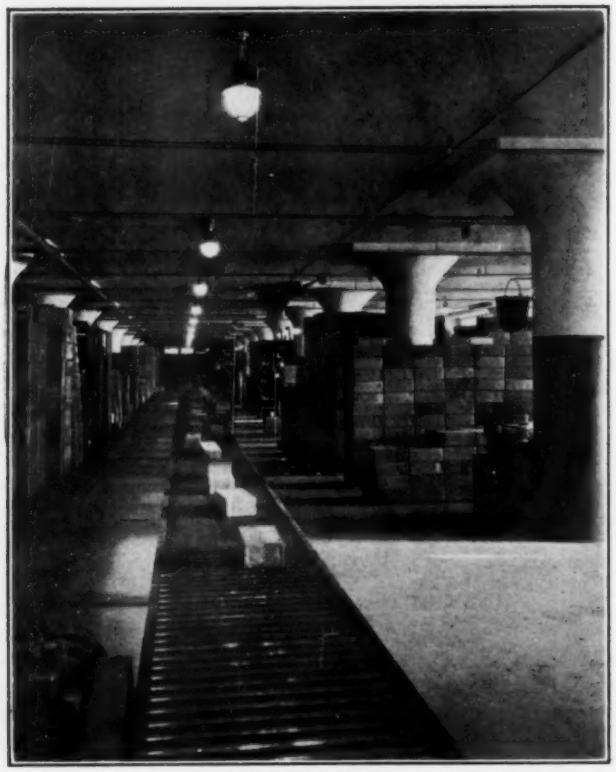

FIG. 11 SOUTH SIDE OF TYPICAL FLOOR LOOP

containers are removed, the boxes are marked by a stencil showing their contents and the bay number where the stock is stored, and they are then weighed. This same movement of the belt brings a new lot of empty boxes, thus completing the cycle.

When the second cycle is started, the stenciled boxes run on a belt which takes them to the second floor, where the conveyor turns back and runs directly overhead to the sealing or nailing machines, according to whether they are corrugated-paper or wooden boxes. The switch making this division is controlled from the first floor at the marker's position.

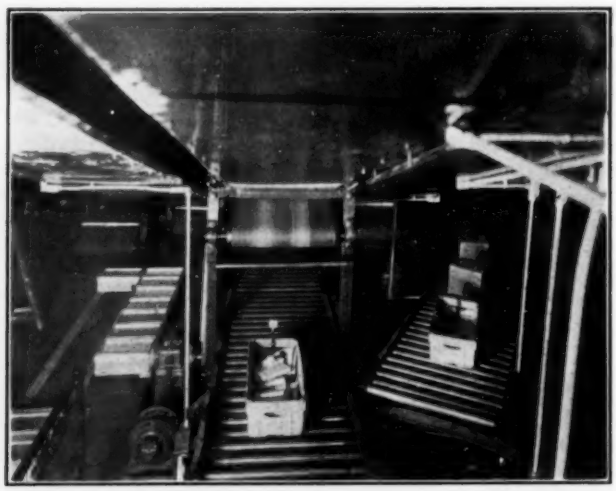

FIG. 12 AUTOMATIC SWITCH

FIG. 13 METHOD OF DRIVING LIVE ROLLER CURVE

SELECTING AND SHIPPING

The orders are received by mail from the distributing houses and are edited, typed, and sent out for either immediate selection or manufacture. Those for selection are sent to the warehouse office on the third floor, where they are sorted for location of

material and sorted so as to get like addresses together and stencils cut for all shipping orders.

Dispatcher's Position. Orders are sent by pneumatic tube to the dispatcher. His position on the second floor is the heart of the entire system. Here the incoming small packed boxes are dispatched to their appointed areas. If they are to be shipped, they can be so switched as to go directly to the correct car or truck by dispatcher. The incoming material arriving by car also passes this position and can be directed to all areas. (Fig. 8.)

There is a large signal board in front of the dispatcher's position which is laid out to look like a bird's-eye view of the critical points of the conveyor system, and by a number of different colored electric lights in the slots, the dispatcher can see whether the distant belts are running, what position the switches are in, and how many and where the boxes are that he is sending out. (Fig. 9.)

Just below this signal board are banks of electrical push-buttons controlling remotely all the belts and switches which the board pictures in miniature, so that the dispatcher has a visual check on the result of his manipulation of the switches.

FIG. 14 GATE SECTION IN RAISED POSITION

FIG. 16 AUTOMATIC "Y" INTERSECTIONS

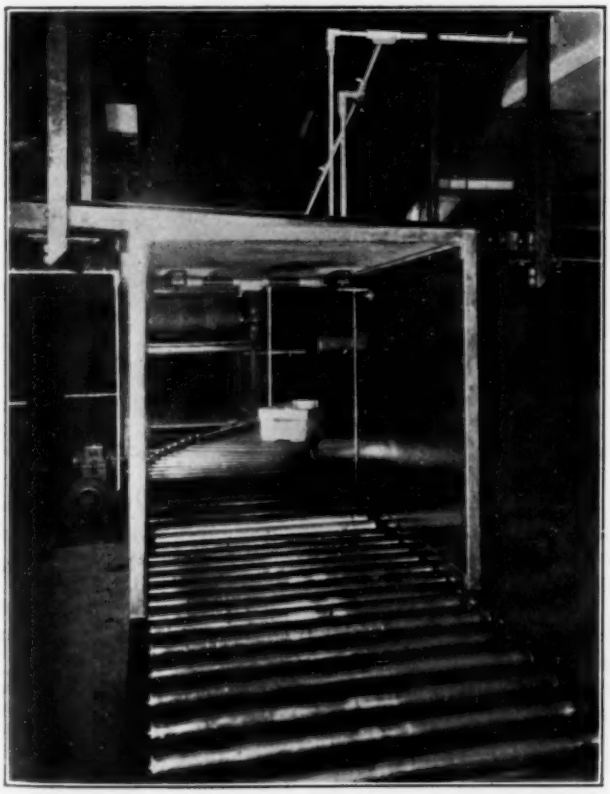

FIG. 15 AUTOMATIC SWITCH SHOWING LIVE ROLLERS AND HOOD

FIG. 17 AUTOMATIC FEEDER BELT AT "Y" INTERSECTION

There is also at the dispatcher's position a microphone and the various controls of an extensive public address system, by which he can transmit information concerning incoming material to the storage floors above and concerning outgoing

FIG. 18 SORTING POSITIONS SHOWING FOOT CONTROL OF SMALL BELTS

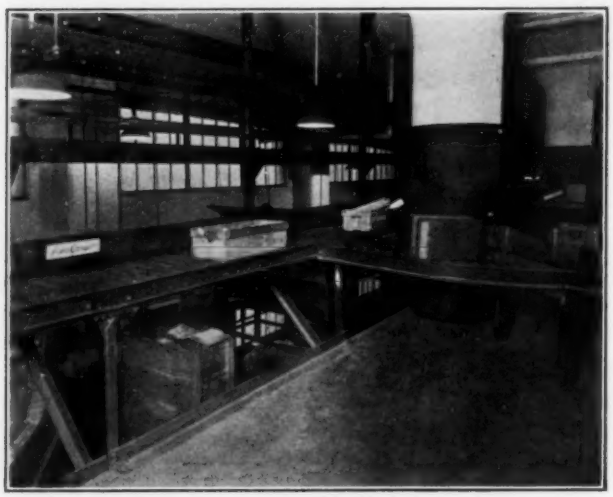

FIG. 19 CHECKERS' POSITIONS SHOWING PARCEL-POST CONVEYOR AND RETURNED EMPTY CONTAINER LINE HUNG FROM CEILING

material to the car-loading positions or the shipping platform.

When the dispatcher receives the orders for apparatus via the pneumatic tube, he places one order in a container, which, when empty, is brought by his position on a belt conveyor controlled by pushbutton.

Containers. These containers are made of wood reinforced by woven wire, and have a small plate of hard rubber on the bottom with two brass spring plates 4 in. apart, lengthwise of the container. (Fig. 10.) These brass springs are connected by wires to the two sides of a telephone jack, which is in a hard-rubber post fastened to the end of the container. When a telephone plug is placed in this jack, a circuit is completed from one brass spring to the other, and in this manner the automatic switching is done.

The plugs are equipped with a colored disk, and as each floor has a color assigned to it, the dispatcher places in the jack a plug with the colored disk of the highest floor nterested in the order. He also places the plugs with colored disks for the remainder of the floors in the bottom of the carrier with the order. Then he presses the button controlling the empty carrier feed

FIG. 20 PARCEL-POST CHECKING AND PACKING OPERATIONS

belt, and the carrier is fed to the upgoing belt, which is traveling at 150 ft. per min. He sets his switches so that the carrier goes directly up to the highest floor interested in the order.

Here the carrier switches off into a live roller conveyor, making a large loop around the floor, and as it passes by the broken package racks, the selectors stationed there examine the order and place in the carrier the apparatus called for, placing the packed stock quantities in their boxes directly behind the carrier with the order number written on them. The selector then removes the first plug and disk and places in the jack the plug and disk for the next interested floor below and lets the carrier go.

The carrier proceeds around the conveyor loop, and by means of the contact points on the bottom works the automatic switch, which diverts it on to a descending belt to the floor below, where it travels around the loop. (Fig. 11.) The packed stock box, because it has not contact points, throws the automatic switch the other way, diverting the box to a descending belt,

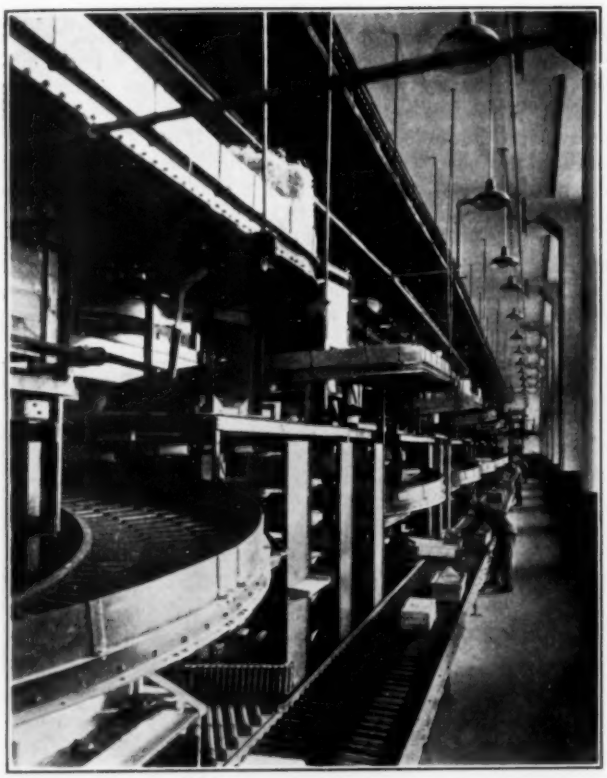

FIG. 21 MISCELLANEOUS PACKING POSITIONS AND SIX STORAGE SPIRALS, MARKING, AND WEIGHING POSITION

FIG. 23 ALLIGATOR SWITCH

FIG. 22 MISCELLANEOUS WEIGHING POSITION AND PUSHER-BAR ELEVATOR

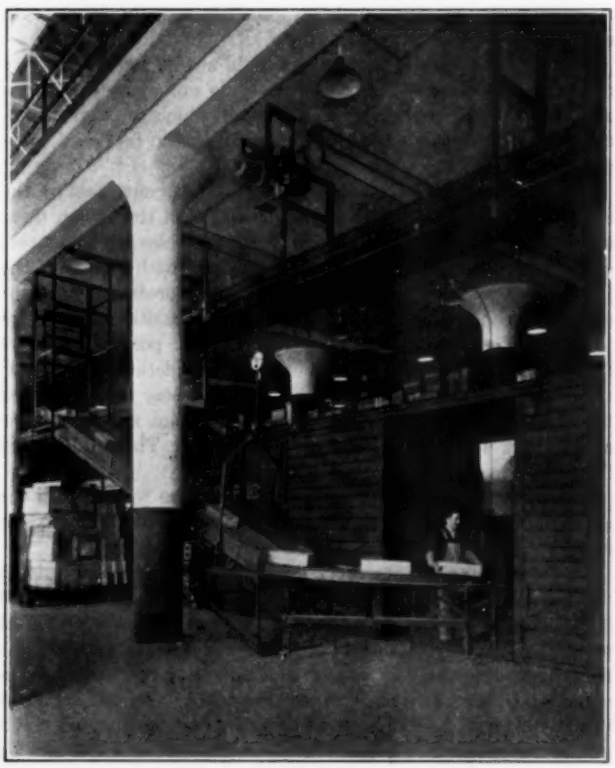

FIG. 24 "LOWERATOR" AND PORTABLE CONVEYOR LOADING CAR ON INSIDE TRACK

going directly down past the dispatcher's position. (Fig. 12.)

The carrier proceeds around each loop on every floor in this manner until the order is filled. Then the last selector removes the last plug, and the carrier travels in the same manner as a packed stock box by the dispatcher's position.

Live Roller Curve. It was necessary to develop a new type of live roller curve which could have its rolls adjusted as to lead, so that the carriers would remain parallel with the conveyor

FIG. 25 SMALL FLAT CAR USED AS BRIDGE

after rounding four curves. This was accomplished by using the live roller principle and a 2-in. belt and snubbing down every 2 ft., so that the belt could take an eighth turn and change direction almost like a rope drive, then slotting the inside frame lengthwise, and by using a clip on the shaft end, the lead can be adjusted within limits. (Fig. 13.)

Gate Sections. The gate sections could not be made of gravity rolls as it is essential that the carriers do not catch up on one another. A belt section was developed which is driven from the live roller section preceding it and which can be raised without shutting off the motor. (Fig. 14.)

Automatic Switch. The automatic switch is controlled by the carrier as described. (Fig. 15.) Just ahead of the switch there are two "hot" rolls connected to opposite sides of a 110-volt circuit. When the carrier passes over them with a plug in the jack, the circuit is completed, and the motor-driven alligator switch responds if it is in the right-hand position and shifts to the left. If it is already in the left-hand position, it stays there. The box, not having means of completing the circuit, throws the switch to the right or compels it to stay there. Mixed trains of boxes and carriers can pass this point and throw the switch back and forth if they are 3 ft. apart. The selectors are instructed to allow 5 ft.

It was necessary for a counting device to be worked into the circuit so that the switch will not be thrown until the box or carrier counting in has counted out on the correct line.

"Y" Section. The conveyor line from the floor above joining the loop on the floor below makes a "Y" section necessary, and if not automatically controlled, would have been a source of trouble. A feeder belt of 4-ft. length was placed in the gravity roller preceding the "Y" section and a floating roll in the down-coming line, so that when a carrier is coming down and depresses the floating roll, it shuts off the motor operating the feeder belt and starts a timed relay, giving the carrier a chance to get on to the loop before the main-line feeder belt is started up again. (Figs. 16 and 17.)

Sorting and Packing. After the carriers and boxes pass the dispatcher, they loop around to the sorters position, where they are mechanically sorted four ways—l. c. l., express, miscellaneous (needing packing), and carload. The sorter does this by pressing a pedal under the box or carrier when it arrives opposite the belt he wishes to sort it on. This pressure elevates two short belts running at right angles between the rollers and carries the box to a belt running at right angles from the main conveyor. (Fig. 18.)

The l. c. l. and express lines take only those packages that are standard packed boxes. They run almost the entire length of the building to the clerks who make out the waybills or express receipts, providing adequate storage for peak loads.

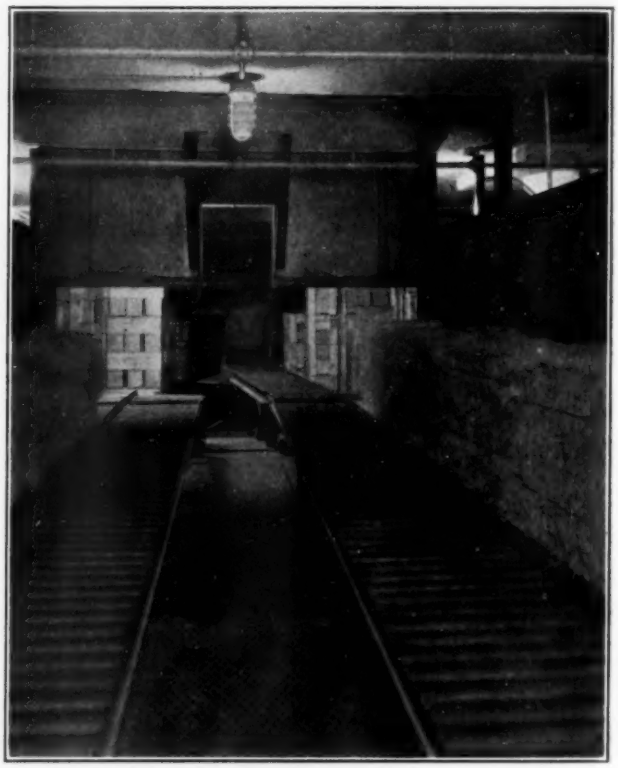

FIG. 26 EXCELSIOR STORAGE BIN

The miscellaneous line takes the containers and the small amount of packed stock boxes to the checkers' positions. (Fig. 19.) Here the checkers place the containers with apparatus going parcel post on a conveyor line going to the parcel-post packing position or transfer the contents from the container into a packing box, which they obtain from a rack conveniently located behind them. (Fig. 20.) The checkers then let the boxes run down a gravity spiral to a packer located on a platform within the spiral and midway between the first and second floor levels. The checker places the empty container on a conveyor line directly above the parcel-post line, which takes the empties back to the dispatcher for reuse.

The packer stuffs the box with excelsior and seals or nails it and lets it continue down the spiral until it arrives on the first floor level, where the spiral empties on a long live roller conveyor. (Fig. 21.) There are six of these spirals all emptying on the same live roller conveyor, where they are marked, weighed, and returned by means of a pusher-bar elevator (Fig. 22) to the second floor, joining the l. c. l. or express conveyors referred

to, and are diverted, as required, by an alligator switch controlled at the scale position. (Fig. 23.)

The boxes, after being accepted by the express clerk, who works along the conveyor line, run down through the second floor and into an express truck trailer stationed in the auto court.

The l. c. l., after passing the waybill clerks, go down through the second floor and out into Building 72 and directly into an l. c. l. car.

The packing boxes going into a car to some distributing house take a fourth sorting line, and the dispatcher directs their course of travel through the remote control of the switches. Only one car is loaded at a time, and this is done by a belt used as a "lowerator," which is lowered by the dispatcher from his position by means of pushbutton control and is recorded on his signal panel by means of lights. (Fig. 24.)

This lowerator delivers the boxes opposite the car door, and when a portable curve section is attached, the boxes run into the car. When the lowerator goes down, its downward movement throws a deflector across the live roller line feeding it, but the actual movement of the belt on the surface of the lowerator is controlled by a floor-operated clutch, which is in the control of the loading gang.

When the dispatcher is sending boxes to a new car position, he announces it to the loading gang through the public address system. He then raises the lowerator he has been using and lowers the one he wants to use. When he presses the button to raise or lower, a loud Klaxon, which is operated on the motor hoist directly above the moving end of the lowerator, warns those in the vicinity of such movement; also the entire bottom of the lowerator that comes in contact with the floor is covered with a hinged plate, which is part of the limit switch, so that if some obstruction were in the way, the limit switch would operate before the weight of the lowerator would come upon it.

In place of bridges across the railroad tracks, small flat cars, 12 ft. by 11 ft. 6 in. with roller bearings, have been installed. (Fig. 25.) These have rings on the four corners and can be lifted out of the way by the crane when cars are shifted, can be rolled along the track to affect convenient crossing points, and can be used to move small loads of material to the dock for water shipment.

The broken-package material selected for the switchboard jobs and sent to the first balcony in Building 72, where the switchboard accumulation racks are, is selected in the same carriers and in the same manner as described and is sorted out on the l. c. l. line and diverted by the waybill clerks to a conveyor taking it to the balcony in Building 72. Here the carriers are unloaded, and they continue on the same conveyor to the dispatcher's position for reuse, joining the other empty container line.

The excelsior-storage bin is suspended from the ceiling of the second floor of Building 71 in the long slot over the general packing line on the first floor. The excelsior is stored on conveyors and is sent to the various packers' positions on the conveyor. (Fig. 26.)

MH-52-7

What Does the Materials-Handling Equipment Manufacturer Need to Know to Make a Successful Installation?

By N. H. PREBLE,[1] DETROIT, MICH.

The answer to the problem of making a successful installation of material-handling equipment is not always simple and, due to varying conditions, is not always the same. In general, however, the following conditions must be examined: (1) Purpose of proposed handling installation. (2) Nature, weight, size, etc., of material or articles to be handled. (3) Capacity required. (4) The path which the material must follow. (5) Details of building or space within which the equipment is to be used. (6) General information as to power available; unusual conditions of temperature, moisture, etc.; erection conditions; and the like. The paper outlines in detail these various items, with a view to assisting the buyer.

THE question as to what does the materials-handling manufacturer need to know to make a successful installation is not easy to answer in any simple terms. One is tempted to say, merely, that he should know everything which can in any way affect the selection of equipment, its design, manufacture, installation, operation, and maintenance. But that, after all, is no answer, as many, if not most, prospective users cannot recognize just what will affect these various points. Furthermore, the user will frequently have only a vague idea of how to get started in the collection of the required information, and not being fully aware of what type of equipment may be available, will be unable to make a proper selection.

In many large corporations, on the other hand, the plant-engineering department will include a division or group specifically charged with the solution of handling problems. This group may have sufficient knowledge and experience to select equipment, arrange all details of its design and installation, and issue complete specifications and drawings, all without reference to or advice from the handling manufacturer. However, even in a case of this kind, it may be well worth while for the user to lay his whole problem before the manufacturer, who frequently, with his more general experience in plants of all sorts, can make valuable suggestions. The manufacturer is also more familiar with new developments in design or methods. From the standpoint of the manufacturer, it is well to check very carefully into the specifications and drawings which may be issued in a case of this sort, as numerous instances have arisen where some detail of construction or design has been overlooked, also where slight changes or possibly major changes would materially improve the operating results of the selected apparatus. The author has in mind an instance which actually occurred, where a user submitted complete drawings worked out in great detail, involving the handling of certain articles on an existing truck. It so happened that the manufacturer to whom these drawings were submitted was acquainted with the details of the problem and the design of the truck, and found immediately that the conveyors were so laid out that they would not operate properly with the trucks which must be used. This, in spite of the fact that the drawings were supposed to be correct, and had been checked and issued as working drawings. Incidents of this sort are not infrequent, and it behooves the manufacturer to be very careful in going over such drawings and specifications as may be submitted to him.

In most plants, however, no such complete drawings and specifications can be made up, as the engineering department is not properly equipped to do this type of work. In order to make our story complete, we will therefore consider this type of user, who has no organized materials-handling department and only a limited knowledge of the means available for the solution of his handling problems. He may perhaps not even recognize that a handling problem exists, and will only recognize it after a suggestion has been made by some outside party.

In preparing our data, the first thing we should do is to examine the purpose or reason for the contemplated equipment installation. In order to clarify this discussion, let us divide handling equipment into classes according to purpose. We find in general, three main divisions:

(1) *Transportation.* Where the purpose is merely to move material from one point to another, vertically, horizontally, or on an incline.

(2) *Assembly.* Where an article is carried, continuously or intermittently, from one work station to another, various parts being added or operations performed while in transit, the article usually remaining on the equipment throughout.

(3) *Processing.* Where some process is performed, such as painting, drying, baking, heat treating, or the like.

The combination of any two or all three divisions will occasionally be required, but practically all handling problems will be found, on examination, to fall in one or more of these main divisions, and a recognition of these main divisions will frequently assist in the analysis of the problem to be solved.

It will immediately be apparent that within each division, certain types of equipment will predominate, but the final selection will depend on a thorough examination of the individual and peculiar requirements in each case, in addition to a mere examination of the purpose to be accomplished. For instance, in the transportation of packages, using that term to distinguish from bulk material, the truck or trailer will, in general, be selected, if the path to be traveled is to vary and is to cover a large area. If however, the area is limited, certain conditions may make a crane more suitable, while if the path is fixed a conveyor will frequently be the final selection.

Bulk handling equipment, as the bucket elevator, the belt, or screw conveyor, will almost invariably fall in the first classification of transportation, although some process such as drying might be included, but it cannot be assumed that in any particular instance the best apparatus for the transporation of bulk material is necessarily of this particular type.

The user must therefore start out without bias, and rather than assume that he needs a certain type of equipment, should state the purpose for which this equipment is to be used, fully and

[1] Vice-president and Chief Engineer, Mechanical Handling Systems, Inc.

Presented at the Third National Materials Handling Meeting, Chicago, Ill., March 5 to 7, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

clearly, and ask for recommendations or bids. In equipment for simple transportation the explanation of the purpose is relatively easy, but it should be remembered that it is possible that in addition to transportation it is desirable to have a certain amount of storage. For instance, on some conveyors for transportation of material from one point to another, particularly in the case of the overhead power-driven trolley conveyor, it is desired to use the conveyor as a storage bank, and if such a requirement is desirable, that fact should be clearly stated.

Where assembly operations are involved, a carefully detailed operation sheet must be made out, covering all operations to be performed, together with a time study of each operation. It will also be necessary to examine the means for bringing the stock to the assembly line and the storage space required for such stock alongside of the line. This work should be taken care of by the user, either directly or through the use of some consultant service. Occasionally the equipment manufacturer is in a position to assist in the accumulation of this information, but the responsibility really devolves upon the user, who is more familiar with his operations and conditions than the manufacturer can be. These studies lead to a final determination of the number of work stations required, time or space for each, and finally the spacing of the work, the length of the line, and the speed required.

When the purpose for which the equipment is to be used comes under the third classification of processing, the time element must again be carefully determined and stated, also all possible information as to the details of the process, the temperatures involved, any special conditions as to high moisture content of the air surrounding the equipment, acid fumes, and the like.

Having determined in complete detail the purpose to be met, one must next turn to an examination of the material to be handled. For bulk material, this must include the nature of the material, its weight, and condition. A statement of what the material is would ordinarily be sufficient explanation of the nature although in the case of some special compounds further details might be given. Weight should be expressed in pounds per cubic foot, with a further statement in some cases as to whether this is dry weight or total weight, including the actual entrained moisture. If the material is any special condition, as wet, sticky, hot, or frozen, these facts should be noted, and where lumps exist the size of the largest and smallest pieces should be given.

If the material to be handled is an article or package, full dimensions and weights of each piece should be furnished. Where the shape is at all complicated, such dimensions should be accompanied by a sketch or blueprint showing full details. The weight of each piece and the material from which it is made should be noted, together with any pertinent comments as to special care required to prevent breakage, marring, scratching, spilling, or the like. This last item is quite important, at times determining the design of equipment, and it is sometimes impossible for the equipment manufacturer to determine how much care must be taken in handling. Sheet-metal parts for instance are frequently finished with a very high finish, in which case scratching of the piece would cause considerable extra work. In other instances, it is not important. The type of finish to be applied might therefore materially affect the selection or design of handling equipment.

Having covered the purpose of the proposed installation and the material in full detail, one should next take up the question of the capacity desired. For bulk material a simple statement as to the tonnage required to be moved per hour may suffice. If, however, the volume or tonnage varies greatly from time to time, maximum and minimum should be noted, and if the equipment is to be used only intermittently, the length of time within which it is desired to move a given quantity must be stated. These conditions of varying capacity and intermittent use may determine the size of the equipment, and in some cases the desirability or economy of a variable-speed driving mechanism. For instance, if one is considering a portable conveyor for unloading a car of coal, it would be possible to use a very small machine which would take a considerable time to handle a full car. However, it may be necessary that the car be unloaded in considerably less time, which in this case would involve the use of a larger machine. This simple illustration shows the importance of knowing the time interval where the equipment is to be used intermittently.

For the transportation of articles or packages the capacity will be determined by the number of pieces of each kind or size which must be moved in a given length of time but one must also know what the sequence of the various pieces is to be, where more than one size or type is to be handled; that is, whether one is to move a large batch of one particular kind, and then the other sizes, or whether these are to be mixed up in the handling. One should also know whether they are moved to an assembly operation or conveyor requiring synchronized speed and the sequence or rotation of the various parts properly to feed such a line.

For assembly or processing operation, this information should be further amplified by details of how closely the articles may be spaced together; that is, the maximum room required around the article for the operations involved. If any special or unusual conditions exist which would affect the loading or unloading of the equipment, no matter what the purpose is, such conditions should be fully explained. It is sometims necessary to design equipment which will unload or load automatically from some other equipment. In other instances, the loading will take place at more than one spot or, on the other hand, may be entirely confined to a limited space, all of which may have a considerable effect upon the equipment.

The next question to examine is the path or paths through which the material must be moved, and until this is fully understood one cannot even start to determine the type of equipment to be used. The best way, and probably the only clear way for, the user to answer this question if the path is at all involved is by means of a layout sketch or drawing, giving a fully detailed plan of the entire area involved, together with full and complete elevations and cross-sections. Alternate paths should be shown, together with notations of obstructions existing, which cannot be removed, or on the contrary, which can be removed if necessary. Such drawings may not always be necessary, but will be valuable, except in the most simple instances, in giving a clear picture. Usually, if such drawings and sketches and elevations are not submitted, it will be necessary for the manufacturer to make an actual inspection of the plant, which may involve considerable additional expense and delay.

With all of this information at hand, an analysis can be started to determine the most suitable type of equipment to meet the particular problem. However, some building conditions may exist which might influence this choice, and as one must have full details of the building or area within which the equipment is to be installed before one can formulate a bid, it is well for the user to supply this information at the same time as that already discussed. This should include full detail in regard to the construction and dimensions of the building within which the equipment is to be used or, if outside, the nature of the ground over which it is to operate. Building information must include all details of the obstructions, such as steam pipes, sprinklers, light fixtures, conduits, ducts, and the like, which cannot be removed. Type of floor constructions should be noted, and if any equipment may possibly be hung from building steel, detail of that steelwork should be shown, with notations as to whether it may be drilled for the attachment of hangers or other structure. In concrete buildings, thickness of the floor should be shown, together with the type and location of ceiling inserts if any exist. Where open-

ings are to be cut through the floors or walls, it should be definitely understood whether the user contemplates doing this work, together with the patching and housing of any such openings himself, or whether he expects this to be done by the equipment manufacturer.

At the same time that the building details are given certain miscellaneous items should be covered. Under this heading come electric current characteristics; a notation as to special atmospheric conditions, if any such exist, etc.; if bids are desired, any unusual condition surrounding the installation of equipment should be explained fully, especially the necessity for the use of union labor, for working overtime, or possible interference with the user's production. If the user has standardized on the use of certain types of devices, such as grease fittings, speed reducers, variable speed transmissions, and the like, such special preferences should be clearly noted. In some instances the user, due to already having in a considerable amount of equipment, would prefer certain very distinct types or makes, and where such preferences exist, this should be explained for the guidance of the manufacturer.

This, then, covers the questions of general physical requirements in a manner which will usually be found sufficiently complete. Assuming the data to have been properly collected and presented, the manufacturer will be able to submit proper recommendations, prepare drawings or designs, and offer bids for the installation.

We must not, however, neglect another phase of the question, and that is the economic side. No material-handling installation, however successful it may be mechanically, can be considered a true success unless it is justified from the economic standpoint; in other words, unless it pays its own way. Usually the question will arise as to how quickly must the investment necessary to make the installation be returned in savings in order to make it worth while to go ahead with the installation. This question cannot be answered without considering the type of installation or equipment under consideration, for the rate of returns which must be expected will vary with different types of equipment. In general, if the equipment is almost certain to remain in use for a long period of time, if its maintenance or actual physical depreciation and its probable obsolesence are low, the rate of return can be considerably below that of some other type of apparatus whose period of usefulness is somewhat limited and whose maintenance and depreciation are high. If the industry or plant into which the equipment is to be placed is in a state of flux, the rate of return must be high. This consideration has influenced the automotive industry, in general, to make a rather blanket rule that no handling equipment shall be installed unless it will return the entire investment within a period of twelve months or less, and in view of the fact that the plants are so frequently rearranged, this ruling is in all probability justified. In other industries and for other types of equipment a longer period would be economically sound.

There is, however, some danger of looking at this question purely from the standpoint of labor saving, perhaps because that is the easiest thing to determine in definite figures. Very frequently, however, there will be other considerations which will be of equal importance, or sometimes of even greater importance. It is conceivable that the total production of a plant can be materially increased; that a very serious congestion in aisles, driveways, or elevators could be reduced sufficiently to warrant a considerable expenditure. In other instances, excessive breakage or damaging of goods might, without at the same time effecting a reduction in labor costs, be a sufficient factor to warrant an installation which in itself would not make any saving in labor costs. Conditions of this sort are not by any means unusual.

One must therefore consider these ends or means in addition to the physical factors which have been discussed. It is found very difficult, however, to lay down hard and fast rules for the gathering of information along these lines. Probably the only thing that can be done is to have a discussion with the representatives of the equipment manufacturers, who will be able in most instances, and always glad, to assist in pointing out what can or what cannot be accomplished to overcome the difficulties or conditions which the user has to face. It is entirely possible that such a discussion will disclose the fact that certain types of equipment which have been recommended from the physical standpoint might be economically unsound, due to excessive expense or some other condition, and the recommendation might therefore be changed to some more inexpensive apparatus which, while not making as great a saving as the other type, would be more certain to pay its way.

MH-52-8

Materials Handling in the Plant of the Goodyear Tire and Rubber Company

By C. C. STUBER,[1] AKRON, OHIO

In the plant described, 964 people are kept busy transporting an average of 1,863,269 lb. of material in process of manufacture over a floor space of 6,443,419 sq. ft. by the use of 17,000 electric power trucks, industrial hand trucks, and platform skids. This equipment would make a train 19 miles long. There are 81 elevators and 29,654 ft. of conveyors. The industrial trucks are under centralized control.

INDUSTRIAL transportation, as applied to our organization, means the one best way of transporting material in the shortest possible time with the least expenditure of money and energy, so that the part played by transportation, in the final cost of the finished product, is reduced to a minimum.

As we know, there has been misconception in the minds of some as to just what is meant by inter- and intra-transportation and what it amounts to in our factory. Such confusion may be entertained when consideration is given to our problem of unloading 77 freight car loads of raw material daily. This requires a careful study of suitable transportation routes. From the staggering number of 1214 transportation routes in the beginning, we have been able to reduce the number to 415 routes.

A personnel of 964 can transport an aggregate weight of 1,863,269 lb. over a floor space of 6,443,419 sq. ft. by the use of 17,000 electric power trucks, industrial hand trucks, and platform skids. If such equipment could be coupled together, it would complete a train more than 19 miles in length, capable of transporting 34,000,000 lb. of material, occupying a floor space of 306,000 sq. ft.

There are 81 elevators distributing truck loads among the various floors.

Revolving independently are some 29,654 ft. of electric and gravity conveyors which are mounted on especially strong and rugged frames. From their remote controls, they can be governed to facilitate and expedite an even flow of material to the various machines along their path. The ease with which material is placed on or taken off the conveyor by the operators is gratifying to note. The conveyors are equipped with safety features.

Such a tremendous capital investment must be economically and efficiently handled, and, in so far as industrial transportation cannot be eliminated, it therefore becomes necessary and a part of the manufacturing process. We know that transportation does add to the value of the product (which is contrary to previous statements), as care must be taken in handling the various elements which go to make up our products. To prevent any of the elements from becoming contaminated by foreign substances while en route may protect and preserve the quality of our product.

By analyzing our transportation problems, our scientific investigations disclosed much lost time and wasted motion among our suppliers, the confusion of transportation deliveries between various departments, and the multiplicity of various different types and styles of truck equipment. We then realized its imperfections. When we realize the amount of internal transportation and why it is necessary to continue to carry back and forth the equivalent of 16 times the weight, for such is the actual handling of 29,812,304 lb. before the finished product is completed at a weight of 1,863,269 lb., is not the total rather staggering?

Fabulous sums have been expended for installation of mechanical or gravity conveyors which were substituted for trucking. Such installations were made on the prominent routes, where the fleets of the greatest number of trucks were operating. When such routes were conveyorized, it not only eliminated the trucking operations, but allowed additional space for production which formerly was occupied by trucks.

The extent to which a transportation system may be extended by an overenthusiastic manager may not only result in a rising cost, through the expense of operating, but may slow up actual production.

For the purpose of administration and accounting, the functions of our transportation organization are divided into the following units:

A Transportation of raw material from our unloading docks to our various warerooms and then to preparatory divisions.

B Transportation of all prepared stock to their respective cushions ahead of assembling divisions.

C Transportation of articles while in the process of being manufactured and manufactured articles to finished-product storerooms.

D Transportation of finished articles from finished-product storerooms to the various shipping departments.

E Transportation of material by electric power trucks.

F Industrial electric-truck batteries-charging division.

Each division is in charge of a foreman and is subdivided into sections controlled by a head supervisor. Each section is subdivided into as many parts as are necessary to render efficient service for the transporting of material, and each of these subdivisions has a supervisor in charge.

Items for consideration are:

A Standard equipment.
B Aisleways.
C Return loads.
D Routing of deliveries in cycles, or one way traffic.

The supervisors are trained for their duties and rights within the organization and are taught all the intricacies of industrial receiving and shipping, such as careful planning and routing, for the transportation man must have a technical knowledge, not only of his position, but also of the material he is handling. This can be obtained only by a systematic study of all the factors which enter into the service of transportation as well as those directly affecting department shipping and receiving.

All transportation suppliers' wage earnings are computed on a piecework basis. All piecework operations include the following:

When material is loaded upon equipment for transporting or stowed in any of the raw-material or finished-product storerooms, the material in question will be segregated according to quality, size, and type and placed in the proper location.

Contributed by the Materials Handling Division and presented at the Akron Meeting, Akron, Ohio, October 21 to 23, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The marking on the various articles will be facing one way when in storage or on equipment, so that the description on articles will be accessible for any one to read. When a supplier is dispatched for material, he will see that just the amount, size, and type, as requested on order, are loaded.

Material, whether raw, in the process of being manufactured, or in the finished product line, must be loaded upon, as well as removed from, platform skid, truck, or conveyor in a satisfactory manner.

In no case shall a supplier push a load of material off a platform skid, truck, or conveyor, as in all cases where this practice is tolerated it may result in considerable damage.

These items are carefully checked to avoid unnecessary repiling of material resulting from slovenly work on the part of the supplier, as repiling causes an increase in the unit cost of the department to which material is being delivered.

When material is delivered to a department for use of the department's craftsmen, the supplier distributes his load in such a way that all craftsmen will be kept busy and so that there will be no lost time in waiting for or going any distance for raw material. The supplier's incentive, of course, is that, operating on piecework himself, the greater the amount of material the craftsmen consume and the smaller the possibility of a delay in the craftsmen's duties, aided by his own elimination of delays in operation, the greater will be his earnings. This is so important and has such a far-reaching effect upon the output of the factory, by keeping the craftsmen contented and maintaining an even and regular distribution of material, that such distribution is not left entirely to the supplier, but is very carefully watched by the transportation supervision cooperating with the production departments. Delays cause a loss in production that not only occasions a loss to the company but also leads to labor dissatisfaction.

Accounting Control

The cost of transportation service is charged directly to the production division from which material is being transported.

Industrial transportation equipment is divided into 44 classes, and a code number is set up for each class. There are 13 classes or codes for electric power trucks, 4 classes for batteries, 22 classes for industrial trucks, and 5 classes for platform skids. All repairs, lubrication, and depreciation are charged directly against a class or code. Industrial transportation equipment is allocated according to production departments, and truck maintenance is charged to the production division according to such allocation.

Delivery Control

A daily or weekly schedule, listing quantity and description of material, is the authority for delivering of material.

Centralization and Control of Equipment

Industrial-truck equipment throughout the factory is controlled and operated under one centralized authority. Without such unity of neutral centralization, each production department would maintain its own trucks and they would become a secondary issue, their real importance not being recognized. While one department would be struggling along with inadequate equipment, due to a sudden increase in production or a breakdown in truck equipment, another department might have a surplus of such service due to a decrease in production or unexpected layoffs. In this way both departments would be operating at a loss. Still other departments would try to obtain more trucks than their quota, so as to have a surplus for a safety margin.

There is also a duplication of effort through the return of an empty truck after making a delivery. Centralized control, whose record depends absolutely upon quality of service and minimum of expense, will route deliveries so as to have a return load at all times. This also relieves congestion.

Such centralization of unit control was established to study and eliminate all waste effort, confusion, and friction between production departments relative to industrial-truck equipment. All electric and hand trucks are numbered, prefixed with a code letter. All truck equipment is divided into 44 classes, according to size and type. Electric trucks are classified in 13 codes, hand trucks in 22 codes, platform skids in 5 codes, and electric batteries in 4 codes. While the allocation of trucks is set up for each of the various production departments, according to their production requirements, the allocation may be changed from time to time, either increasing or decreasing the number in the fleet.

Standardization of Industrial Transportation Equipment

Until recently the value of engineering service was not recognized in regard to industrial transportation equipment. In the past each department maintained its own idea of certain types and styles of trucks to perform the operations pertaining to its production, with the result that when a production department was discontinued or certain operations were eliminated in the process of manufacturing certain articles, such equipment became obsolete. The salvaging of this equipment, entirely or in part, gave the management the idea to study the needs of the plant's production as a whole and then design a type of truck chassis that would be interchangeable throughout the factory.

A standard type of running gear or chassis was designed with the utmost flexibility in steering and turning through narrow aisles and around sharp corners. This truck chassis could easily be equipped with various types of racks or bodies best suited to the needs of the different departments, and if production department or operation was discontinued, these superstructures could easily be removed at a small cost. The result of this investigation is that, instead of the multiplicity of sizes and types of trucks formerly in use—that is, from a variety of 49 types of one line of trucks—there now are but four types of truck chassis, with a number of interchangeable parts, which answer all the requirements of the original 49 types.

All industrial four-wheel trucks are equipped with standard couplers. Such flexibility enables operating the electric tractors in any industrial truck cycle.

Where material is consumed slowly, the platform-skid method of transportation is adopted. In the installation of the platform-skid method a standard height is maintained in order to obtain a flexible service unit, so that the transporting can be performed by either hand or electric lift truck. When it is necessary to move platform skids a short distance only, it is entirely satisfactory, as well as efficient and economical, to equip such platform skids with casters or wheels, to eliminate the necessity of waiting for the arrival of a supplier with a transveyor. The craftsman can then move the platform-skid load whenever necessary without the loss of time.

It has been found that properly selected electric trucks, powerful, compact, and the minimum in weight, are well adapted for certain types of transportation service, and a fleet of 73 electric power trucks is helping to keep down the cost of transportation. All electric-truck battery compartments are so designed and built that they will receive any style of battery that we employ. Such interchangeability of batteries allows the service of each electric truck for the 24 hours.

Inspection and Lubrication

Trucks are first inspected for condition before being lubricated; that is, all bolts are tightened, and those small miscel-

laneous repairs which are necessary to place a truck in first-class condition are made. A pressure lubricating method is standard equipment. Inasmuch as trucks are always equipped with some sort of a lubricating system, such as greasecups, oilwells, oilcups, etc., which in time become clogged with dirt and grease which has hardened due to certain conditions existing in the factory, not only has the pressure system of lubrication proved considerably more effective, but it is less expensive than the former method.

When lubrication is completed, the truck is given a thorough cleaning. All foreign substance is removed from casters, running wheels, and deck. All trucks are painted yearly.

A card index is maintained, recording the truck number, the number of the production department to which the truck was allotted, the date the truck was lubricated, and the date the truck was repaired. Such information affords an opportunity to nvestigate the reason why any particular piece of equipment must be repeatedly oiled or repaired.

Maintenance

Observation of industrial transportation equipment under actual service, relative to wearing qualities, length of service, and ease of operation, discloses many mechanical defects in the design.

Considerable experimental work has been done to determine the right type of wheel construction, especially the best width, as floor maintenance seems to be exceedingly high. The results of this investigation are found in the recent development of a satisfactory tire wheel for the industrial truck wheels and casters. It is gratifying to note the ease of motion while the truck is in operation and the absence of truck vibration.

A centralized truck-repair department has decreased the truck maintenance cost considerably, for as soon as a defect is noticed in a truck, the truck is immediately placed in the repair department for repairing or overhauling.

What has been accomplished may be seen from the evolution of transporting material by hand to conveyor. The progressive steps are:

A Hand.
B Two-wheel baggage trucks.
C Four-wheel flat-deck trucks.
D Hand lift truck and platform skids.
E Electric tractor and four-wheel flat-deck trucks.
F Electric transveyor and platform skids.
G Rearrangement of machines.
H Mechanical power conveyors.
I Force of gravity.
J Linking together machines into one unit.

Symposium on the Economics of Delivery Service

Commercial Operation of Electric Trucks and Trailers Compared With Gasoline-Operated Vehicles

A recent treatise on the development of electric service in the smaller towns and rural districts contains the following significant statement: "The ability to ship by truck or rail from and to any point and available power supply at almost any place have made it possible for American industry to remove and remold itself at will."

These papers cover gasoline and electric vehicles and discuss the application of motor trucks operated over public highways to the service of industrial plants. The economic place of the truck is approached from two angles:

1 Its function in promoting (a) the flow of raw and semifinished material into the factory or plant; (b) the movement between plants under a single management or from any of these plants to the warehouses or branches; and (c) the final physical distribution to customers or consumers.

2 The ownership of the trucks engaged in the productive process as (a) by the industrial plant itself or (b) by outside specialists working as contract or common carriers. Operation and maintenance of "owned" trucks may be assigned to various plant departments or even to a subsidiary company. The conditions affecting the preferred type of control or organization are considered.

The several authors also take up at some length the growth of motor express and freight companies, especially emphasizing their relation to the industrial plants, particularly of the type that is manufacturing goods that are shipped in small lots and sold through outlets dealing directly with the general public.

Economic Aspects of Gasoline-Operated Commercial Vehicles

By R. E. PLIMPTON,[1] CHICAGO, ILL.

INTERNAL transportation, or the materials-handling facilities entirely within industrial plants, has been the subject of many comprehensive papers presented before the Materials Handling Division. These have covered the control, application, and design of industrial trucks and tractors confined to the buildings or the private roadways within manufacturing establishments. Little attention has been given, it appears, to an equally important matter, namely, the general economics of the highway motor vehicle engaged in one or more phases of the process of production. Hence the aim of this paper is to discuss the contribution that has been made by the motor truck and the public highway, wherever they may be used in the service of manufacturing establishments.

By way of introduction let this fact be emphasized: details of construction and methods of maintenance will be improved as time goes on, but the pressing problem is to get the best use from the well-developed truck equipment now on the market and from the fairly well-organized haulage companies.

The field of application of the truck and its utility to the industrial plant is steadily increasing. In recent years higher truck road speed has been a powerful influence in decreasing plant inventories, with attendant lower capital charges for material in process of production. Highway developments are permitting the elimination of bottle necks caused by congested freight terminals in many of the large metropolitan sections, while in sparsely settled parts of the country the highway furnishes a more direct route than available railroad facilities. These better roads have helped sizable towns to grow up miles away from any railroad. Indiana is said to have 686 towns lacking steam-railroad service. Of this number 166 possess small industries. These receive raw material and ship goods entirely by truck, and largely by vehicles of the common-carrier variety.

The influence of the highway on manufacturing establishments has been so obvious that sometimes its importance passes almost unnoticed. But studies made in the last year or so have given us a national perspective on the problem. The report of the Committee on Recent Economic Changes[2] refers in several places to the "prevailing tendency toward geographical decentralizing of production." Manufacturing has moved to the country, it is asserted.

"The ability to ship by truck or rail from and to any point and available power supply at almost any place have made it possible for American industry to remove and remold itself at will." This quotation[3] from a discussion of the increasing use of electricity in the smaller towns and rural sections is supplemented by a statement that the construction of highways and the increasing use of motor trucks have served to equalize plant marketing conditions between large cities and small communities.

That industry is taking full advantage of the highways in "removing and remolding itself," is brought out in another investigation.[4] A meat packer would supply a local market readily accessible by truck. Dealers within an 80-mile radius are served with crackers and cookies not more than 24 hours old. The tremendous expense of trucking in metropolitan centers is elimi-

nated. These are some of the reasons for new locations of plants or branches given in the Metropolitan Life report. Nearness to markets is the reason advanced most frequently for changes by the sixteen thousand plants from which information was received. Better shipping facilities, especially trucking in New York State, lower trucking costs in Rhode Island, and excellent auto freight service in Ohio, were cited as important advantages in moving either to the outskirts of the larger cities or to more isolated smaller places.

The highway also had its place in new locations selected because of nearness to raw materials, the Metropolitan Life survey indicates. A creamery in Texas is quoted: "We run trucks and pick up all our cream, and we wanted to be near the supply of production." A manufacturer of orange products shifted from one city to another in the same state to be "nearer the center

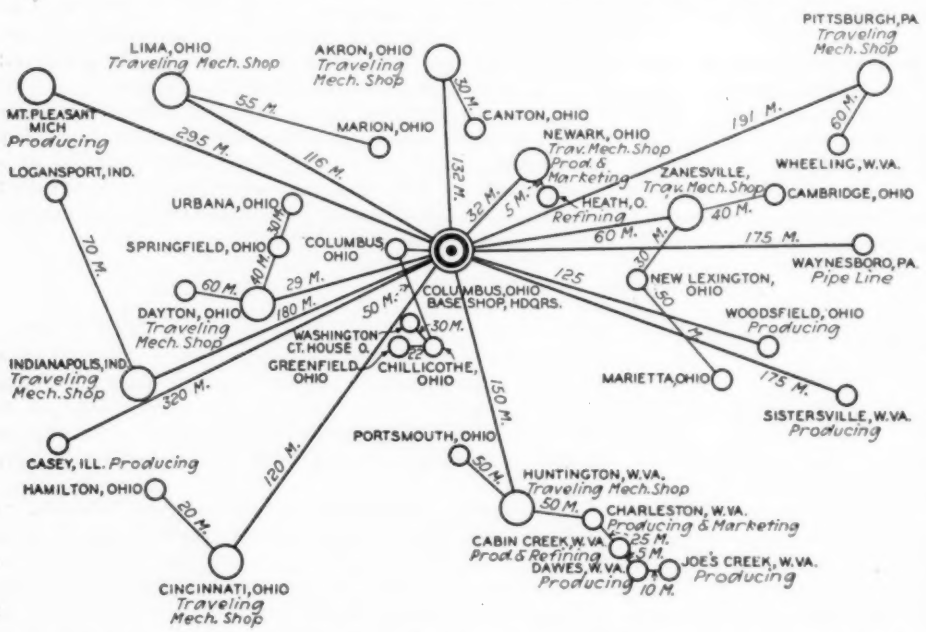

FIG. 1 ROUTES OF CENTRAL DIVISION OF MOTOR TRANSPORT DEPARTMENT OF THE PURE OIL COMPANY WHICH SERVES PRODUCING, REFINING, AND MARKETING IN THE MAINTENANCE OF AUTOMOTIVE EQUIPMENT

of the ton-mile haul on the oranges which we draw from the packing houses throughout southwestern California." One reason for the site chosen by a paper mill locating in Washington was a large number of small stands of white fir and hemlock that could be reached by short auto haul.

ORGANIZATION AND CONTROL

The same acumen displayed in selecting plant location should be used in the truck operation. Who should have the responsibility for the highway vehicles? Should each department using trucks regularly control the operation of certain assigned units, while other parts of the plant having only occasional need for truck service must beg or borrow the trucks ordinarily used elsewhere? To avoid lost motion, to cut down empty or only partly loaded mileage, to keep down the investment and equipment by using the smallest number of units possible, to have one boss rather than half a dozen for the drivers and maintenance force—for these and other reasons there should be a centralized and responsible authority in control of all the truck work. It is necessary to stress the point because most industrial plants, and other users of trucks for that matter, operate their vehicles in the most unorganized and casual manner. Just what this authority is, and the place it has in the main corporate organization, will depend on the use made of the trucks and on whether they are owned by the corporation itself or by some form of commercial carrier.

Unless there is an expert abreast of the subject all the time, how is the purchasing department to know whether incoming material should be taken over at the vendor's plant or whether a price that may be quoted by the vendor for delivery at the purchaser's plant is more advantageous? If delivery is accepted at the vendor's plant, then can the moving be done best by the buyer's own trucks or should the service be purchased from a haulage company? These are problems that are encountered whenever raw and semi-finished materials are to be moved.

Unless such an expert is available, how is the production department to know the best method for moving goods in process from one plant to another? The plants may be a few miles apart in the same city or 75 or 100 miles, and in different towns. The situation may call for use of the corporation's trucks, for the services of a drayage company, or for the use of a motor express or freight company operating on regular schedule. But certainly it needs competent attention

Unless expert advice is available, how is the sales department to know when the highway should be used, and what form of truck movement (owned or hired) is the most economical? Economy here must be judged of course not only by the mere saving of dollars and cents, but by the time saved. There are many other advantages that may be gained in the saving of expense for crating or boxing, and in the good-will that prompt and dignified service may create with the public as well as with customers. All this would be important if the goods were shipped f.o.b. to the plant, but a direct saving would be possible if the selling price included delivery at the customer's premises, as often happens in these days of mass distribution.

Unless expert advice is available, can the accounting department allocate the truck expense among departments? Certainly one of the main functions of the centralized authority here advocated would be to keep adequate cost and performance statistics, not only of the owned vehicles but also of outside trucks. It should also be responsible for carrying out and devising a practical scheme so that the truck expense can be distributed in proportion to the service used by stores, production, sales, or other departments, or by the customers, if the charge is passed on to them.

SUBSIDIARY COMPANY

Let us now consider more definitely the authority that should be made responsible for the trucking activities. A wholly owned subsidiary formed to specialize in trucking and allied activities in many respects offers a clean-cut solution to the problem. The separate company, however, must be dealt with as a corporate entity and required to stand on its own feet. That is, in its function of giving or perhaps buying truck service, the

subsidiary should pay for all it gets from the parent and related companies and charge for whatever work it does for them. This scheme can be more easily carried out if the trucking subsidiary has offices, staffs, and storage and repair facilities apart from those of the manufacturing establishment. The function of such a separate company is primarily to handle work for one customer, but if the customer's demands are irregular with occasional peaks or heavy demand, it may be desirable to hire outside trucks. The use of rented trucks has been advocated in order to try them out on new work and thus determine the right size and number to be purchased. This practice would not be required in establishments that have expert transportation advisers, of course.

A few of the larger corporations using trucks have seen the necessity of a motor-transport department more or less on a par with sales, manufacturing, and other main divisions, reporting directly to the president of the company. This implies usually that the trucks are a large item in the total operating expense and also that they are working for many different departments. They may be widely scattered, as with the integrated type of petroleum companies which own everything from oil wells to roadside filling stations. When all phases of the process of production and distribution are concentrated in a fairly small area, the motor-transport activities may be organized as shown in Fig. 1.[5] This is merely one division of the Pure Oil Company, to which are assigned 250 trucks and 50 passenger automobiles. The set-up would differ slightly in the producing fields of Texas, or in New York and nearby states, where marketing is the chief activity of this company and of its truck equipment.

Ordinarily the truck work will be under some such department as production, traffic, or sales. The White Motor Company, which prides itself on handling its truck equipment as efficiently as any of its customers would, has a city transportation section to pick up goods at local vendors and freight stations. The foreman of this city transportation section reports to a material supervisor, in charge of the storerooms and materials-handling facilities inside the plant, and the supervisor in turn reports to the works manager, so that the truck operation is essentially under the production department. It is said that this centralization of authority has enabled the company to cut down the number of trucks about one-third and still give good service to the various departments.

In the divisions of the Chrysler Corporation, where the movement is almost 100 per cent between factories in various parts of Detroit, the highway truck work comes under the traffic department. The Chrysler Corporation organization includes what is known as an inter-plant transportation department, headed by a superintendent who reports to the director of traffic. The Dodge Brothers and Plymouth plant trucks are likewise operated under the supervision of the traffic-department heads.

Just why the truck work should be assigned in one plant to the production department and in another to the traffic department is sometimes hard to understand. The latter is the authority on rail transportation, and is usually in a good position to apply sound principles of operation and to make a selection as between road or rail if either can be used—this provided it has kept abreast of developments in motor transportation. But a competent staff in the production department is in charge of the internal industrial trucks, and if the volume of work they handle is large compared to that required of the highway vehicles, it is undoubtedly good policy to give this staff the complete authority.

[5] Furnished through the courtesy of Leo Huff, Manager Motor Transport Department, Pure Oil Company, Chicago.

The sales department has the best claim to the control of trucks when they move the product to widely scattered retail sources or dealers. With some petroleum companies perhaps 80 per cent of the trucks are operated for the marketing or sales division of the business. The sales department or its local manager has direct control of the drivers, lays out their routes, and supervises their sales and collection activities. A motor-transport section of the sales department is concerned with the selection of truck equipment, design and construction of auxiliary devices, and with provisions for storage and repairs. The motor-transport section may have a measure of authority over the drivers as regards proper handling of the equipment, but this is likely to be more or less advisory and exercised only through cooperation with others in the sales department.

The same division of authority may be necessary or desirable in manufacturing plants where the work is concentrated in one group of buildings. Very often the master mechanic and his department in charge of plant maintenance can best be made responsible for the maintenance of the highway equipment. If the volume of road movement is fairly evenly divided between the other departments, then the master mechanic can supervise the operation of the highway vehicles as well.

Inter-Plant Movements

Goods in process, as distinguished from the finished product, form the main part of the inter-plant movement here considered. This is true whether the movement is from the vendor to the company plant engaged in fabrication or assembly, or, with a larger corporate organization, between specialized plants. Good management in either case would involve, first, a constant flow of material arranged to satisfy production schedules and keep down inventories of material in process; and second, the elimination of hand work and idle time of the trucks, by a close coupling of the highway vehicles and the materials-handling system of the industrial plant. The first of these is a matter of scheduling or dispatching to a large extent. The tendency with large plants is to reach out and pick up the goods at smaller vendors within local territories, say, within a radius of 15 miles. If the vendors are situated further away than that, then they take the initiative and send small shipments by motor carrier. Such service is available in a thickly populated industrial section from points as far apart as Cleveland and Buffalo or Chicago and Detroit, of the order of 300 or 400 miles.

The second requirement, involving the elimination of idle time and hand work, is being promoted by the design and layout of buildings. New factories put up since the war are usually designed for off-street and under-cover loading and unloading of motor trucks. Columns and posts are located to help and not hinder the truck movements. Platforms are being built the same height as the truck floors, even when this involves a ramp for the small and lower vehicles. A depressed-runway construction is considered a great advantage in the Chrysler plant, where a 51-in. concrete unloading ramp with depressed floors permits trailers to be backed against a platform exactly the height of the trailer floor. Electric industrial trucks can then be run directly on the floor of the large truck or trailer.

The magnitude of the annual trucking done by a large industrial concern is shown by the following figures, furnished through the courtesy of J. H. Myler, director of traffic for the Dodge Brothers Corporation:

Division	Work handled, lb.	Miles operated
Chrysler	433,880,911	1,093,097
Dodge	351,236,928	884,901
Plymouth	82,643,976	202,212
Totals	867,761,815	2,180,210

About 25 per cent of the materials for the Chrysler division is handled by the trucks of the inter-plant transportation department, while 70 per cent moves by rail or boat, and the other 5 per cent by trucking companies operating on regular routes.

Other materials-handling facilities can be brought directly to the truck, and are to a limited extent. Portable conveyors can easily be arranged to carry packaged goods directly into the truck body; a tramrail system, Figs. 2 and 3, that eliminates all lifting of dressed meat in and out of the truck, is used between Jersey City plants of the Swift Company by the Motor Haulage Company. The new R. H. Macy department store building in New York City, in addition to a 100-ft. truck platform, has two elevators on which loaded trucks can be moved to any floor.

The truck body itself may be removable, so that the load can

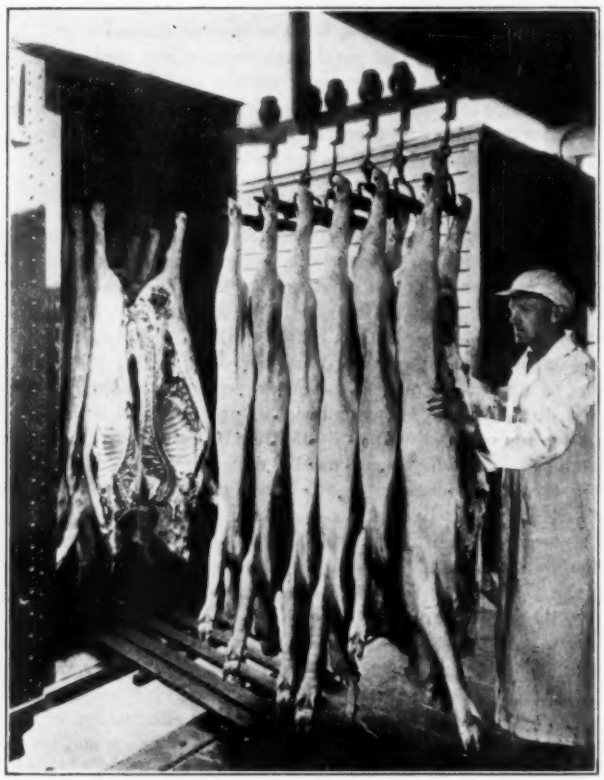

FIG. 2 SPECIAL BODY EQUIPMENT, LINKING UP WITH PLANT MATERIALS-HANDLING FACILITIES, SUPPLIED BY A COMMERCIAL HAULAGE COMPANY TO JERSEY CITY BRANCHES OF A LARGE PACKING COMPANY

be packed inside the plant or can be discharged at some point more convenient than the truck dock or platform. This work can be going on with extra bodies while a load is moving over the road. The International Motors Company gets the effect of a demountable body by the use of wheeled aluminum containers, Fig. 4. These carry castings from the company's foundry at New Brunswick, N. J., to its plant at Plainfield, 14 miles away. Fixed tracks are required for getting the container on or off the truck. If these tracks are not available, the container can be transferred to an ordinary road trailer, and then to the loading platform. The design is considered an improvement over the construction used by eastern railroads, which latter requires an overhead crane for transfer from truck to freight car.

Handling fuel and other supplies not part of the manufactured product is often a serious problem. The Lukens Steel Company has recently embarked on an unusual project for moving fuel oil from the refinery to its plant at Coatesville, Pa. The plant process continues 24 hours a day, and hence the delivery takes advantage of the commonplace but infrequently utilized fact that the highways are open at night as well as during the more normal working hours. Vehicles and their oil, fuel, repairs, and maintenance are supplied by a commercial haulage

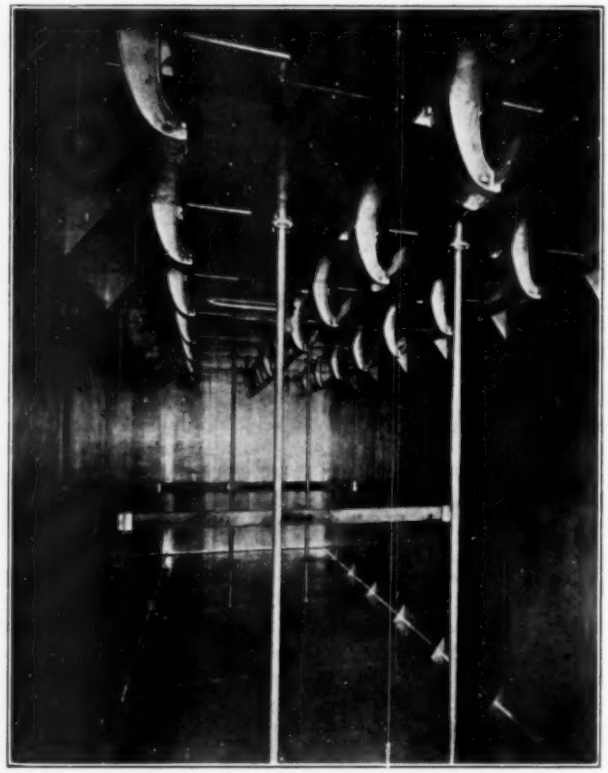

FIG. 3 OVERHEAD RAILS CARRIED ON BRACKETS SUPPORTED FROM THE ROOF OF THE TRUCK BODY. NOTE CROSS-PIECES TO SECTIONALIZE THE LOAD OF HOG CARCASSES

FIG. 4 CONTAINER OF 15,000 LB. CAPACITY USED FOR CARRYING CASTINGS FROM FOUNDRY TO ENGINE PLANT OF TRUCK MANUFACTURER. ONE MAN CAN DISCHARGE IT

company on a per-mile charge basis. According to a report in a recent issue of the *Commercial Car Journal*, the contractor charges about 0.6 cent per gallon delivered, while the railroad charged 0.89 cent a gallon. An estimated saving of $100,000 a year will be made, and this will soon offset the $30,000 the company spent for a concrete highway to connect the public road

with its storage tanks. Another saving is in handling the oil at the steel plant. It cools only about 30 deg. during the two-hour or 30-mile trip, and can be discharged without being heated. Previously, when railroad shipments were on the road possibly for several days, reheating was necessary. This movement is made in trains, Fig. 5, consisting of a tractor drawing one semi-trailer and another four-wheel trailer. These carry 2800 gal. and 2100 gal., respectively. Six White tractors and eight sets of Fruehauf trailers are assigned to the service, so that an extra pair of trailers can be stationed at each end while the others are on the highway.

A Sales-Department Adjunct

With the product finished and ready to ship, there enters the troublesome problem of physical distribution, one that requires all the best efforts of sales and traffic departments if the goods are to be laid down at the doors of the dealer or other customer at the lowest cost and, what is even more important, at the time and in the quantities wanted. The truck may serve by picking up the goods at the plant's shipping room and dropping them at the consignee's door, or if he has his way, at the back alley or other receiving entrance. For this work vehicles owned by the manufacturer may be used in metropolitan sections and their immediate suburbs, within a radius of 25 or 30 miles from the factory or warehouse.

The territory covered by "owned" trucks may be extended to a 75-mile limit when the shipment involves special goods or special handling of them. For example, the tank trucks used in hauling gasoline, Fig. 6, are not available for carrying general merchandise, and so the oil companies are forced to depend largely upon their "owned" service. When the drivers must also be salesmen, and perhaps stack, stock, and display the goods as well as collect for payment, the longer routes may be covered in vehicles devoted exclusively to the manufacturers' service. This would apply usually to goods of a perishable or semi-perishable nature—food products, bakery goods and the like, or to soft drinks—involving frequent attention to customers and a return of empty containers and bottles.

Some of the larger baking companies have a system by which the drivers buy the truck chassis while the company supplies the body. The drivers are then paid a percentage of gross sales as salary, plus an allowance for maintenance. They must pay for the storage of their vehicle, and keep it in first-class operating condition. This scheme seems to be used only when the vehicle is light and comparatively inexpensive. A more general practice is to require each truck put out for sales purposes to bring in a minimum return in the way of sales. If this is not attained, it usually means a careful study to determine whether the route is justified at all, or less frequent service can be given, or the sales ability of the driver is at fault.

Cooperation and Transportation

By far the larger part of present truck movement, at least of manufactured goods, is in conjunction with the older rail or water carriers. A manufacturer in Brooklyn, say, with a shipment destined for a hardware jobber in Phoenix, Ariz., may call upon his haulage company to move the shipment to the Bush Terminal, there to be transported by water through the Panama Canal. Arriving at San Pedro, Calif., there are fifteen or twenty truck operators waiting to carry the shipment to Los Angeles and into the terminal of the "Desert Express" trucking company, which makes regular trips over the 476-mile route to the capital of Arizona. There if the wholesaler happens to be disposed to send the complete shipment to a dealer, say, in Florence, Ariz., he can have the goods immediately transferred to a local motor carrier operating a network of routes out of Phoenix (see Fig. 7), Alabam's Freight Company, Inc., which finally sets the goods down at the hardware dealer's store.

If this same shipment happened to be consigned to a hardware dealer in Winner, South Dakota, the drayage company would still be called upon but would deposit the goods at a railway freight station where they would be loaded in a west-bound merchandise car for Sioux Falls, S. D., or possibly for Minneapolis first and then made up again in another car for Sioux Falls—after which a railroad-controlled trucking company would pick up the shipment and move it over the 224 miles to Winner, in the south central part of South Dakota.

Railroad Activities

As the economic place of the truck is beginning to be demonstrated, a few of the railroads are operating revenue road services. One of the first evidences of this cooperation has been "internal"

Fig. 5 Nearly 5000 Gallons of Fuel Oil Are Carried by This Road Train
(This form of transportation supplies the complete requirements for a large steel company.)

Fig. 6 New Form of High-Speed, Light-Capacity Delivery Is Being Adopted by the Oil Companies
(This vehicle can make 30 m.p.h. and carries 750 gal. of gasoline.)

use of trucks by the railroads. Trucks either owned or hired are handling movements of merchandise between freight terminals of a single or of more than one rail carrier. They are also being used to distribute l.c.l. shipments from one station to smaller points, where the truck is cheaper than the former peddler-car method. Truck applications of this kind have no direct effect on rates or on the contact of the shipping public with the railroad. Shippers still deliver goods at the carrier's station and consignees must pick them up there. What the truck does is to cut down operating expenses of the rail carrier and incidentally help the shipper by speeding up the through movement.

The change in attitude of the railroads toward the truck has undoubtedly been hastened by its success in moving non-revenue freight, such as the supplies formerly distributed by work trains or sometimes in revenue freight cars. The Great Northern, it is reported in recent issues of *Railway Age*, has 38 trucks scattered over its system, used for the movement of small lots of materials by its stores, maintenance, bridge, building, and other departments. The Southern Pacific operates a supply unit from its West Oakland headquarters. Once a month six trucks and thirteen trailers deliver and pick up material from sections, signal towers, and crossing watchmen in a territory of some 30 square

miles near San Francisco. Between these monthly trips short hauls are made to the stores, laundry, and commissary departments. The trucks cover about 4300 miles a month at an average cost of slightly under 23 cents a mile. This same railroad, according to a report presented last year to the American Railway Bridge and Building Association, estimates that motor trucks will save 50 per cent of the cost of moving materials between Chicago and Milwaukee. This has the advantage of the ordinary truck movement, in that late-afternoon pick-ups can be delivered at destination early the next morning. Two handlings of the goods are saved by placing a road trailer on a rail car for the line haul. (See Figs. 8 and 9.) Rates of 30 cents a hundredweight include free pick-up and delivery service on minimum shipments of 10,000 lb. If the shipment is more than 20,000 lb.

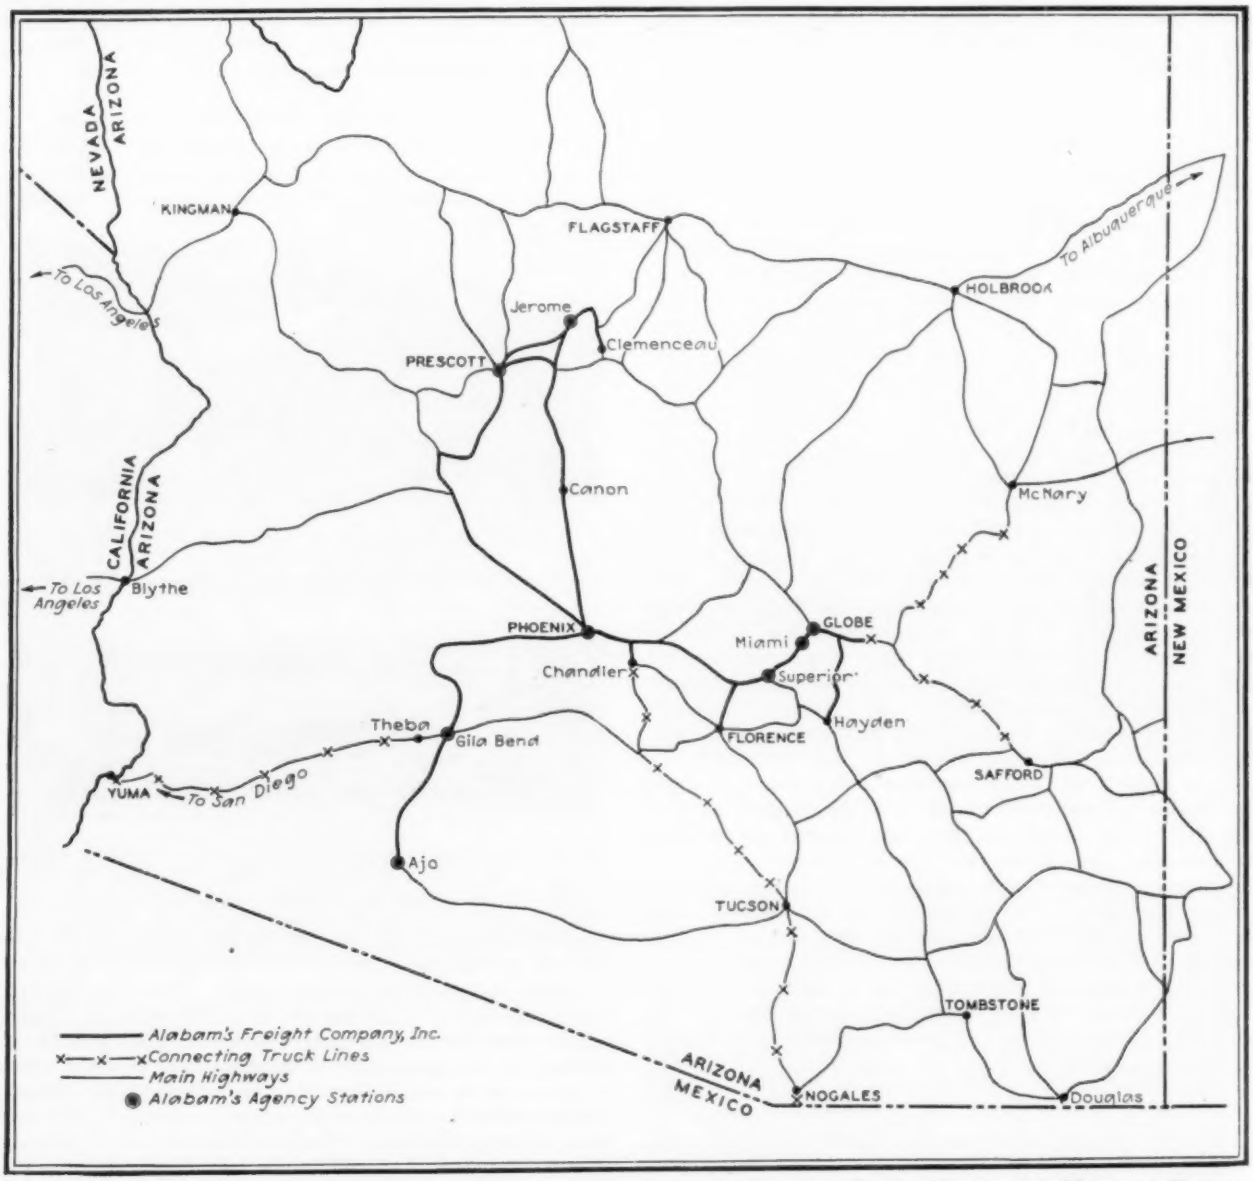

FIG. 7 FROM THE DISTRIBUTING CENTER AT PHOENIX A SINGLE TRUCKING COMPANY COVERS NEARLY 600 MILES OF HIGHWAY ON REGULAR SCHEDULES

with the motor car or push car, and 75 per cent of the expense of handling with work trains.

In taking to the highway for short hauls of their own small-lot materials, the railroads are adopting the same principle that the motor carriers in effect advocate by their operation of scheduled and other truck services.

The natural tendency of the railroads is to retain the line haul on rails and to make use of the truck for the movement at either end. Service of this kind has been worked out by the Chicago, North Shore, and Milwaukee Railroad on the 90-mile haul between Chicago and Milwaukee. This has the advantage of the ordinary truck movement, in that late-afternoon pick-ups can be delivered at destination early the next morning. Two handlings of the goods are saved by placing a road trailer on a rail car for the line haul. (See Figs. 8 and 9.) Rates of 30 cents a hundredweight include free pick-up and delivery service on minimum shipments of 10,000 lb. If the shipment is more than 20,000 lb. the rate is 20 cents a hundredweight. That this plan may be extended to cover other parts of the country is indicated by the tentative proposal of one railroad-owned motor carrier to span an 80-mile section of poor road on one of its routes by hauling the trucks on flat cars over the railroad.

The electric interurban railroads, which move such a large volume of manufactured products from factories in Ohio and Indiana to the automobile-assembling plants in Michigan, have issued tariffs indicating that pick-up and delivery charges may be absorbed in whole or in part by the rail rates on much the same

basis that trap-car service is given directly to industrial plants by the steam railroads. If the weight of the shipment and the revenue it involves are not sufficient, the shipper can have the goods picked up or delivered at this plant merely by paying a slight extra charge.

One interurban electric railroad in Michigan has acquired control of a trucking company which not only operates over regular routes, but also does a general city cartage business. But as a rule the interurbans turn the truck work over to a separately owned cartage concern, to which is paid a specified allowance. The use of this cartage service is optional with the shipper, who can use his own trucks at terminals if he so prefers.

The Pacific Electric Railway, serving a large part of southern California with its rail lines, has formed a subsidiary express company, designed to provide door-to-door service at rates that include the complete movement. Existing cartage companies are hired to make the pick-ups and deliveries, while the intermediate movement is over the rail lines. This service reaches some 50 cities, and within three months after it was started early this year, it was reported that 245 industries were being served. Of these, 210 had not previously used the Pacific Electric rail service.

Thus in the Central West and in California the electric inter-

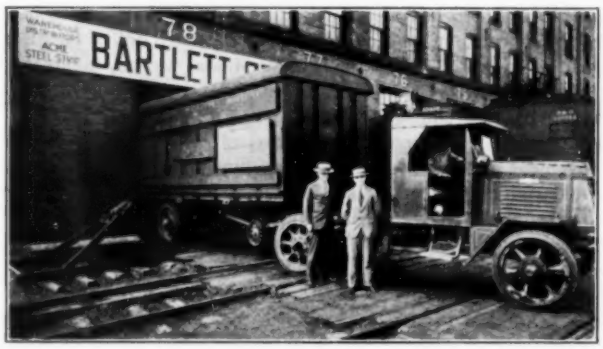

Fig. 8 Road-Trailer Service Over the Highway Extends the Service of an Electric Railroad to Chicago Industries

urbans are offering the store-door delivery available for years in Great Britain and Canada. This complete service was characteristic of the early development of the motor-carrier lines. The truck service is given through subsidiary companies by the Boston & Maine in Massachusetts, the St. Louis Southwestern in Arkansas, and the Chicago & Northwestern in South Dakota. But only a few of the steam railroads of the United States have seen fit to provide either the through or terminal truck service. An approach to it in New York City and St. Louis is given because of a combination of physical conditions and of railroad competition, and does not indicate any general adoption of the policy by the rail carriers.

As has been pointed out in this paper, something akin to store-door service is available in most cities by the employment of cartage companies. But the final step advocated by shippers is yet to come. The railroads would then be responsible for the complete movement. All shipments now moved by shippers or drayage companies to and from the freight houses would be handled by a single company. This might be a cartage company under contract with the railroad, or one owned by the latter.

The steam roads are not convinced that the service is a necessity, generally speaking. But where street congestion is constant and serious, where yards and freight stations are limited, the store-door service might help both the shippers and the railroads, according to one railroad authority. The number of vehicles for cartage and the number of freight cars would both be reduced. Quicker movement of freight would be possible, and economies would be effected by both parties. In any scheme of this kind all the road charges would be passed along to the shipper.

Freight-house facilities for l.c.l. deliveries could be reduced about one-half, one authority in the trucking business has estimated, with what he calls "regulated store-door delivery."[6] This would provide for the smaller shipments up to one or one and one-half tons. Deliveries could be made to the greatest number of consignees at one time and that time would be off the peak of automobile traffic in the business and shopping cen-

Fig. 10 In the Mountains of Southern California, Not Penetrated by Railroads, the Motor Carrier Is an Essential Factor in Physical Distribution

ters. One vehicle might serve one building or one city block, whereas under the present uncontrolled condition the one vehicle may make collections or deliveries at such widely scattered points that the result is a large number of partly loaded trucks getting in each other's way and in the way of passenger automobile traffic.

---

[6] Wm. J. Duffy, General Manager, Big Three Inc., Boston, Mass. at 1929 Transportation meeting of the Society of Automotive Engineers.

Commercial Motor Carriers

One industry that watches all its costs closely, namely, the department stores, has found it desirable both to hire and own trucks. These stores are in the habit of operating their own delivery vehicles, partly on account of the volume of movement available and partly because of the prestige their name carries on well-kept equipment. That this is not controlling, however, is shown by the fact that a separate organization (The Eleto Company) is maintained as the delivery department of some of the largest New York department stores.

The drayage conditions in 88 of the larger cities are reflected in a study made early this year for the traffic and receiving group of the National Retail Dry Goods Association. Of 135 stores replying to a questionnaire, 19 use their own trucks only for drayage work, while 110 use outside or cartage-company service exclusively. The rates paid vary widely, but average 11 cents a hundredweight, with most of the replies indicating amounts between 5 and 15 cents a hundredweight. A minimum of from 10 to 50 cents is charged for each shipment or package handled.

Attempts have been made to form delivery companies owned jointly by several retail stores or other shippers, but as a rule there have been too many owners and too much competitive spirit for these to work out well. Consequently a more common practice is for a specialist, such as a cartage or delivery company, to handle the work in city and suburban territory. A contract or common motor carrier makes the longer hauls. When such service is available, the ownership and exclusive use of trucks may easily become a luxury—and an expensive one. The owners are partaking in individual transportation, dished up in a most uneconomic style. The individual is too often one small box or package, while the transportation unit is waiting and willing to carry anywhere from a two- to a five-ton load.

The commercial service available to the manufacturer may reach practically every town or village in the metropolitan districts. One Chicago haulage company makes daily trips to 125 towns or communities. These are worked on eight different routes. About 40 miles is considered the maximum length of route. Since each one averages 50 stops, the 80-mile round trip represents a good day's work, sometimes 10 to 11 hours, for the driver. Quoted rates are 40 cents a hundred for the 40-mile haul, with a minimum of 75 cents per shipment. Included in this base rate is pick-up at the customer's premises and sidewalk delivery to the consignee. The pick-up work is done usually in the afternoon by delivery vehicles from short runs, or by trucks of the same company used mainly for city haulage. In fact, the suburban delivery is considered an extension of the drayage service to accommodate good city customers.

Most of the shipments handled by this company are sent prepaid, it is understood. More and more manufacturers and their branches are "absorbing the freight." This is perhaps a method of lowering selling prices, but the point of significance here is that with purchased service the delivery expense to be charged against each order is definitely known. This might not be the case if the work were handled by "owned" trucks. At least the actual expense would be harder to determine accurately, and in most cases would be greater.

Beyond the 40-mile suburban zone the motor carrier operating under permit or franchise from state authorities comes into the picture. Small shipments may be moved by bus companies primarily engaged in carrying passengers and their personal baggage; larger ones, by express or freight lines concentrating on the movement of property.

Packages carried by busses are limited in size, say, to 100 lb. weight and in volume to 10 cu. ft. Only a small amount of space is available and the service is intended to cover quick delivery of small-lot material at two or three times the rate charged by truck or rail. Ordinarily the movement is from terminal to terminal, although the driver may make deliveries to consignees directly on the route. A rate structure based upon weight (or volume) and distance is used by the larger bus companies. Special rates apply for newspapers, ice-cream containers, and other shipments requiring unusual handling. The charges for an express service recently announced by the Greyhound Lines on its Chicago-Muskegon division vary from a minimum of 25 cents for 10 lb. or less for the first 25-mile zone up to 45 cents for a haul of 200 miles. The charges in the 151- to 200-mile zone are shown by the following extract from the Greyhound express tariff:

Weight, lb.	Volume, cu. ft.	Rate	Weight, lb.	Volume, cu. ft.	Rate
1–10	.	$0.45	56–60	6	$1.15
11–20	1	0.55	61–65	.	1.25
21–25	2	0.65	66–70	7	1.35
26–30	3	0.70	71–75	.	1.40
31–35	.	0.80	76–80	8	1.50
36–40	4	0.85	81–85	.	1.60
41–45	.	0.95	86–90	9	1.70
46–50	5	1.00	91–95	.	1.80
51–55	.	1.10	96–100	10	1.90

Freight and passengers may be carried in a vehicle designed for combination service, as shown in Fig. 10. This is used on a mountain run of the Motor Transit Company out of San Bernardino, Calif. During the summer-resort season, goods and passengers are handled in separate vehicles, but at other times a single vehicle is sufficient.

Extensive systems of motor carriers concentrating on the movement of property over regular routes and on fixed schedules are developing in many sections of the country. These are often referred to as freight lines, but to a large extent they give an express service, with pick-up and delivery included in the tariff rates. Sioux Falls, S. D., Wichita, Kan., Phoenix, Ariz. are centers of networks, each developed under one corporate ownership. Another type of operation, comprising central terminals for truckers on different routes, is found in such places as Nashville, Tenn., Indianapolis, St. Paul, and Minneapolis.

The motor common carriers (they really are that since they hold themselves open to serve the public at large) establish their rates as a rule upon the basis of l.c.l. freight charges. These have been found fairly profitable for hauls up to 50 miles, but for longer trips are not usually adequate unless the movement is heavy in both directions. Most truck lines follow the railroad freight classification, and have special commodity rates dictated by their local conditions. Taken the country over, the rates vary with locality just as do those of the railroads. The following list gives class rates in cents per hundred pounds for a 50-mile haul:

	Class			
Location	1	2	3	4
Minnesota	31.5	26.0	21.0	16.0
California (southern)	45	40	35	30
Kansas	46	38	31	26
Indiana	46	39	31	23
North Dakota	53	45	34	28
Arizona	65	60	55	45
Texas	65	65	45	45
California (northern)	100	95	40	85

The spread between Minnesota and northern California may seem considerable, but the one is based upon l.c.l. freight charges, while the other is for haulage over poor roads to mountain resorts. Another difference is that Minnesota lines are offered business the year round, while in California most of the business is handled in the three summer months. The Minnesota Railroad Commission has established the local l.c.l. rates as reasonable

and maximum, and requires that five or ten cents a hundred be added to them for ground-floor, pick-up, and delivery service. In Kansas and Texas the rates are higher, of the order of 15 or 20 per cent, than charged by the railroad. This in the belief that the service (pick-up and delivery) as well as the cost of operation justifies the increase. The lines out of Grand Rapids, for which the Michigan rates are quoted, give free pick-up service only for 1000-lb. shipments. More and more motor carriers are adopting the practice of charging for picking up small shipments. Many shippers with trucks they use for city work, prefer to make their own deliveries at the truck terminal; the goods can then be handled at the most convenient time, and without congesting the shipper's loading dock with outside trucks.

That the inter-city trucking business is still in the individual-ownership stage, is shown by conditions in the automobile center of the universe. A compilation made by the Detroit Board of Commerce indicates that 68 carriers operating under permits from the State Utilities Commission have their terminal in the city. These have a total of 288 trucks or tractors. The average number of power units per carrier is less than five, it will be noticed, while 21 are listed as having only one truck. The largest company has 27 trucks and 46 trailers, and operates from Detroit to Lansing, Jackson to Pontiac, Jackson to Lansing, and Detroit to Jackson, Homer, and Albion.

By far the majority of operators in the inter-city trucking field have a radius of operation of less than 50 miles. This is borne out by an investigation made by the Railroad Commission of Texas, with the following results:

Length of route	Operators	Per cent
10 miles and less	9	3.41
20 miles and over 10 miles	55	20.84
30 miles and over 20 miles	58	21.97
40 miles and over 30 miles	48	18.17
50 miles and over 40 miles	26	9.84
60 miles and over 50 miles	14	5.31
75 miles and over 60 miles	16	6.06
100 miles and over 75 miles	12	4.55
150 miles and over 100 miles	21	7.95
Over 150 miles	5	1.90
Totals	264	100.00

From these figures it will be seen that 74.23 per cent of the operators cover 50 miles or less, while only 14.40 per cent cover 75 miles and more. The results apply of course directly to a large agricultural state, but are believed to be typical of most of the states in the country. In some of the industrial sections the movement between manufacturing establishments is justifying much longer hauls.

The increasing scope of the regular trucking services was pointed out in a report submitted by the Hon. Clyde L. Seavey of the California Railroad Commission to the 1929 annual convention of the National Association of Railroad and Utilities Commissioners. To quote from this report:

> A comparatively few years ago the motor truck was confined to hauling l.c.l. freight of a relatively high value for short distances varying from 35 to 75 miles, but in recent years the length of haul has been gradually extended until at the present time it is not unusual for shipments to move three, four, or even five hundred miles. Likewise the nature of the commodity transported is rapidly changing. Such articles as iron and steel, cement, and even crushed rock, which we ordinarily associate with the rail movement, are now being handled in trucks. Dairy products and other perishable freight move under refrigeration for distances in excess of 200 miles. Part of this movement is complementary to the rail haul, but a large part is tonnage directly taken from the railroads.

The truck transportation, according to Mr. Seavey, obviates the terminal handling and transportation cost, permits shipment in smaller units, and for short hauls at least results in a material saving in time. But he points out that while the truck type of transportation is needed, it should be stabilized to the same degree as other types of transportation have been. The private-contract carriers who cannot be placed under the jurisdiction of any regulatory body are indiscriminately cutting rates below the rail rates or the common-carrier truck operators subject to regulation. Many state commissions have received complaints from shippers utilizing the private-contract carriers who have been unable to obtain redress for loss and damage to their shipments or have been unable to obtain a settlement of C.O.D. collections, the report indicates.

The remedy for this situation, which is more or less prevalent all over the country, is largely in the hands of the shipping public. If they will patronize the regular carriers, whether motor or rail, because of service rendered and facilities available, and not take advantage of bargain reductions, they will quickly put the established carriers, particularly in the trucking field, on a basis where they can be of the best service to the public.

In conclusion, the author would call attention to the economic necessity of (1) wise centralization of authority when "owned" trucks are operated; (2) using a combination of road and rail services for long hauls of small-lot shipments; and (3) patronizing well-organized motor carriers for concentrated shipments between plants and for the last stages of physical distribution.

Discussion

CLINTON BRETTELL.[7] On the eighth page it is said that where merchandise was moved by "owned" rather than "hired" trucks "the actual expense would be harder to determine accurately, and in most cases would be greater." The writer's experience as a large fleet operator does not coincide with these statements, inasmuch as large fleets could afford to employ trained transportation and maintenance men and to enjoy all the economies of large purchasing power, specialized equipment, etc.

A representative of an automobile truck company says that small electric cars could be operated 35 to 40 miles daily with entire safety. The writer's experience in the Macy fleet is that 35 miles under ideal conditions is the maximum safe limit for small electrics, although higher mileages are occasionally attained.

The many economies of the electric over the gas truck were pointed out in the paper. The writer's comment is that the lack of flexibility and "cruising radius" of the electric, unless it had year-round work on short hauls, would be a serious handicap to its economy. It is the experience in the Macy fleet, particularly with the advent of cheap light gas cars, that while these cars might be slightly more expensive for a couple of months of the year when they would be operated on short runs and in traffic congestion, their adaptability to long-run work the balance of the year, where electrics could not be used but would have to lie idle, would give an overall advantage over the electric under those circumstances for the year as a whole.

A representative of a trailer manufacturer presented the many advantages of trailer operation. The writer's experience with demountable bodies instead of trailers, which seem to give many of the benefits of the tractor-trailer combination with the added advantage of being able to move the bodies close to the loading points and to various floors in the building, combined with easier handling in congested traffic in the part of the city where the Macy store is located, proves the demountable body a more desirable unit for that purpose.

JAMES W. COTTRELL.[8] The success of a company-owned motor-

[7] R. H. Macy & Co., New York, N. Y.

[8] Technical Editor, *Commercial Car Journal* and *Operation and Maintenance*, Philadelphia, Pa.

truck fleet often depends on its assignment in the organization and the amount of cooperation between it and other departments of the business. In most cases, the fleet should have a separate identity and should be able to show a profit. If each department of a business owns and operates its own trucks, each department will try to keep on hand enough trucks to meet the maximum demand of the department. This of course is not an efficient arrangement.

Mention has been made of the desirability of forming a separate subsidiary company to own the motor-truck fleet. An example of such a separate company is the Equitable Auto Company, of Pittsburgh, which supplies motor trucks for the electric, gas, and street railway companies of Pittsburgh. This company operates a sort of drive-yourself service, merely furnishing vehicles which other allied companies operate. This drive-yourself plan works well in many instances where the using department prefers to furnish and control the drivers.

The value of a separate fleet organization compared with the plan of separate department "ownership" and management of trucks is illustrated in the experience of a large manufacturing company in Trenton, N. J. A few years ago several different departments had trucks, and there was no arrangement for cooperation between departments. As a result, whenever a department had need for a truck, a man would go out and stand in the driveway outside the factory and hail the first truck driver who came along and induce the driver to come in and do the hauling for that department.

A keen truck dealer made an analysis of the transportation requirements of this plant and suggested the formation of a truck transportation department serving the other departments. The suggestion was carried out, and the newly established department furnished better transportation facilities at less cost. Incidentally, the number of trucks required was less than under the former arrangement.

While it is obvious that cooperation between different departments using motor transportation and the fleet department furnishing the transportation is desirable, the fleet department is not always given full recognition.

The fleet superintendent of a large dairy in the Middle West had an opportunity to show the value of cooperation between other departments and the fleet. He attended a conference of department heads and heard one of the branch managers bring up the question of hauling ice to the branch. The manager, after shopping around, obtained the price of 10 cents per 100-lb. for hauling the ice to the branch. The branch manager thought this a very reasonable price. The fleet superintendent offered to do the work for 5 cents per 100, and of course was given the job. Afterward, he let it be known that he could do the hauling for nothing, if necessary, as he has trucks going from the downtown section to the branch empty each day, a fact which the branch manager did not know.

The convenience of truck transportation often justifies its use, even though it costs more than other mediums of transport. If export shipments must "make" a certain boat or a special shipment must go on a certain train, trucks frequently are used between factory and pier or railroad station, even though the shipping points may be many miles' distance from the factory.

A very successful inter-city trucker has kept his customers against price cutting by furnishing a high grade "always-on-time" service. A large part of his hauling is from manufacturing plants which must rely upon regular shipment.

Convenience is one of the factors favorable to the use of trailers in certain fields. Trailers are usually looked upon as a means of increasing the pay load of a given vehicle or of reducing idle time of the power vehicle. In certain applications they have the important advantage of helping shippers. An illustration of this condition is the shipment of tires from factories in Akron, Ohio, to automobile factories in Detroit. Tires come out of the plant in an almost steady stream and are moved across the shipping platform into trailer bodies, which become large bins on the platform. This arrangement reduces handling on the platform, as it is not necessary to unload the tires on the platform and then reload in a vehicle.

Demountable bodies have been used successfully for some time on heavy-duty trucks and are also in use on light trucks. In the heavy-duty field the Cincinnati Motor Terminals Company uses demountable bodies for the exchange of l.c.l. freight between railroads entering the city of Cincinnati. These bodies are handled by overhead cranes, installed in the freight stations for that purpose.

An example of use of demountable bodies on light trucks, in which the body becomes a part of the plant served by the truck, is the James Vernor Company, of Detroit, Mich., makers and bottlers of ginger ale. The bodies, which are used interchangeably on Ford and Chevrolet trucks, are loaded and unloaded by an electric crane on a monorail which extends over the sidewalk. When the truck arrives, the body is hoisted from it and placed on a dolly inside the plant. This dolly and body are moved by hand to an escalator where cases are unloaded and transported to the second floor. The empty dolly and body are pushed to the other side of the room where cases are delivered from the plant by a gravity conveyor. The load is made up in accordance with a shipping order and held on the dolly until the next truck arrives. Actual time required for exchange of bodies is less than three minutes.

An overnight haul frequently is the unit of measurement of truck transportation. Today's production in one factory is delivered to another plant or to destination by the next morning. Truckers seek to extend their field of activity by extending the distance over which a shipment may be carried between, say, 6 p.m. and 7 a.m. To meet this requirement, manufacturers are offering high-speed heavy-duty trucks. A 10-ton truck designed to travel at 35 miles per hour and one of 8-ton rating designed for the same speed were recently put on the market and more are expected to follow. It is obvious that trucks of this capacity and speed greatly extend the radius of operation of "overnight" trucking.

MARTIN J. CONWAY.[9] The author has given an excellent paper on motor-freight movement as undertaken today and to be expected in the future. The writer cannot do better than to substantiate the information the author gave in referring to the hauling of heavy fuel oil.

The Lukens Steel Company owns and operates a fleet of 14 trucks of various makes and sizes for interplant haulage and short-haul delivery of steel plates and flanged heads to the many customers who in these days of low inventories require speedy deliveries.

Practically all of the raw material moved into the plant and of the finished plates moved out of the plant is handled by rail, which requires an in-and-out movement of about 2600 cars monthly.

One item in this car movement was the shipping into the plant of 40,000,000 gal. of fuel oil yearly from Marcus Hook refineries, a distance of 39 miles from refinery to the steel plant, entailing a freight bill of $356,000 yearly. This oil movement presented a real trucking problem, and several studies were made of the possibilities of a saving, as the route over which the motor trucks would have to pass was anything but desirable. The only favor-

[9] Fuel Engineer, Lukens Steel Company, Coatesville, Pa. Mem. A.S.M.E.

able point was that there is a good hard road for the total distance.

Accordingly with the aid of the engineers from the equipment manufacturers, Lukens Steel Company made a survey of the proposed operation which entailed studies of the minimum weight and horsepower of equipment which would carry the maximum pay load, which would be within the highway laws of the Commonwealth of Pennsylvania, and which would operate safely and easily, guarantee uninterrupted service, require the lowest maintenance cost over a prolonged period, and present a pleasing appearance on the highway. All of these features received their share of study, as the route over which the trucks were to travel had all of the elements in its short length that could be expected on a long cross-country run—steep grades, short-radius curves, crowned roads, narrow congested highways, traffic lights, and railroad crossings. (See Fig. 11.)

After ascertaining that the operation of transporting fuel oil to the plant could be performed with motor-truck equipment with as much ease as with railroad equipment and with the assurance

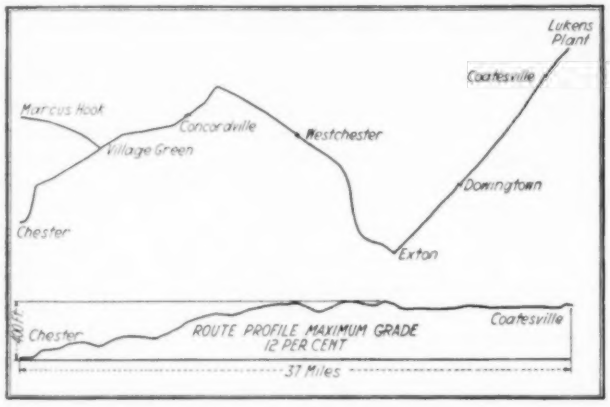

FIG. 11 MAP OF THE ROUTE

of an uninterrupted supply at a saving in the cost of transportation, the Lukens Steel Company decided that the proper course of procedure would be to contract for this service through one of the large haulage contractors whose business it is to operate, superintend, and service contracts similar to the one the Lukens Steel Company wished to place.

After a thorough investigation of the proposition, submitted by six bidders, all being qualified by repute and financial stability to undertake the work, the contract was given to the Motor Mileage Corporation, whose organization has since proved more than equal in meeting all emergencies which of necessity arise in an undertaking of this magnitude.

The Motor Mileage Corporation equipment for this work consists of six Model 59 White truck tractors, six Fruehauf semi-trailers, six Fruehauf four-wheel trailers, one Model "AP" Mack tractor truck, and one Highway four-wheel trailer for this unit. The specifications were as follows:

WHITE EQUIPMENT SPECIFICATIONS FOR MODEL 59 TRACTORS

Engine used in tractors: Bore, 4 3/8 in.; stroke, 5 3/4 in.; piston displacement, 518 cu. in.; maximum net brake horsepower, 100 at 2000 r.p.m.; maximum torque, 320 ft-lb. at 1000 r.p.m.; compression ratio, 4.03.

Reduction range (combination, transmission, and rear axle): 8.9–1 to 109–1 in seven steps.

Range in ability (ability being expressed as a ratio of tractive effort at the tractor driving tires to the gross train weight): When loaded to 72,000 lb. gross, 1.7 to 22.6 per cent; road speed of train at 200 r.p.m., 28.3 m.p.h. to 2.3 m.p.h. in seven steps.

Tire equipment used: 42 × 9 dual pneumatics on driving wheels of tractor; all other tires, 40 × 8; total number of tires on train, 18; total number of 40 × 8 tires, 14; total number of 42 × 9 tires, 4.

Braking: Westinghouse air-actuated brakes on all wheels of tractor, on two wheels of semi-trailer, on two wheels of the four-wheel trailer.

Safety devices: Airbrake system so designed that, should trailer break loose, brakes become automatically set on trailer; safety chains provided between semi-trailer and four-wheel trailer; tractor provided with two legal headlights, two marker lights, and rear vision mirror; trailers provided with combination rear marker light and tail light; tanks painted on end to attract attention of vehicles driving in same direction at night and to show the same as dead-end sign on the highway.

MACK EQUIPMENT SPECIFICATIONS FOR MODEL "AP"

Chassis: Six-wheel chassis, four-wheel drive; driving units, chain and sprocket drive.

Wheelbase: 165 in. between front and first set of rear wheels; 52 in. between two rear sets of wheels.

Weight: Chassis weight, 15,000 lb.; gross load allowed in the State of Pennsylvania, 36,000 lb.

FIG. 12 MODEL 59 WHITE TRUCK TRACTOR, FRUEHAUF SEMI-TRAILER, AND FRUEHAUF FOUR-WHEEL TRAILER

FIG. 13 MODEL "AP" MACK TRACTOR TRUCK AND HIGHWAY FOUR-WHEEL TRAILER

Tires: 40 × 8 front and 40 × 8 dual rear on each of four rear wheels; pneumatic tires.

Brakes: Service brakes on four rear wheels; type, Westinghouse air brakes; internal expanding brakes; brake surface, 574 sq. in.; emergency brake, 16-in. disk on propeller shaft.

Front axle: Center-point steering; reverse, Elliott.

Rear axle: Two solid I-beams, drop forged.

Wheels: Steel disk.

Transmission: Selective, four speeds forward and one reverse; Hypoid gear jackshafts.

Frame: 8 × 3 × 5/16 in. chrome-nickel pressed steel, heat treated.

Gasoline tank: 40 gal. capacity.

Starting and lighting: 12-volt Northeast system; 135-watt generator.

Motor: Model "AP," six cylinder; bore, 5 in.; stroke, 6 in.; brake horsepower, 144 at 1600 r.p.m., 155 at 1800 r.p.m., 159 at 2000 r.p.m., piston displacement 706.86 cu. in.; compression ratio, 4.78. to 1; cylinders cast in block; cylinder heads cast in pairs; governor speed, 1650 r.p.m.; crankshaft bearings, 3 7/16 in. diameter; crankshaft counterbalanced with balance weights forged integral; timing gears, drop-forged chrome-nickel steel, case hardened.

Magneto: Robert Bosch.

Carburetor: Stromberg.
Radiator: Finned tube, back of engine; air circulation by blower on flywheel; thermostat control on water circulation.
Speed: Maximum speed, 28 m.p.h.; average speed, 18 to 20 m.p.h.
Driving ratios: First speed, 57.92 to 1; second speed, 30.32 to 1; third speed, 16.02 to 1; fourth or direct, 9.05 to 1; reverse speed, 69.82 to 1.

The oil hauled by this equipment is the heaviest grade of Bunker "C" produced, ranging from 3 to 10 deg. B., and difficulty is experienced in pumping it at normal temperatures.

Tractors and semi-trailers were included as part of the equipment because it was thought necessary that a full train should be uncoupled during unloading and the tractor be released to take back the empty train while the oil was being heated preparatory to unloading.

Until the present it has not been found necessary to uncouple the tractor from the train for this purpose. As soon as the train arrives at the unloading platform, steam is connected to the coils in each tank at the same time that the unloading connection is made. Steam is turned on, and the unloading pump started simultaneously. This arrangement heats the oil sufficiently while unloading to prevent delay. Another feature is the fact that the oil, being loaded hot, drops only approximately 30 deg. while in transit, the time averaging $2^1/_2$ hours. During the hot summer months it was not necessary to use steam at the unloading platform because the temperature drop en route did not exceed 15 deg.

Author's Closure

Probably the best way to answer Mr. Brettell's opening statement is to quote completely the statement of the paper with which he disagrees. This follows: "More and more manufacturers and their branches are 'absorbing the freight.' This is perhaps a method of lowering selling prices, but the point of significance here is that with purchased service the delivery expense to be charged against each order is definitely known. This might not be the case if the work were handled by 'owned' trucks. At least the actual expense would be harder to determine accurately, and in most cases would be greater."

When the delivery is handled by purchased service, the shipper ordinarily pays separately for each package or order. The cost, therefore, is very clearly and definitely known. But when the shipper's own trucks are used, the process of determining costs is much more complicated. It is difficult to allocate general or overhead items of expense to the Delivery Department. Even though the total costs are included, there is no way of determining unit cost for an individual order or delivery, except by dividing total number of orders and deliveries into total delivery costs. This method of taking averages may be satisfactory for practical purposes, but certainly would not give as accurate results as when the delivery cost for each package is paid for separately.

The other point with which Mr. Brettell disagrees is that: "the expense . . . in most cases would be greater." As the paper repeatedly asserts, it relates to the application of motor trucks for and by manufacturing establishments.

In the majority of instances, trucks in this service would carry small-lot shipments to rather widely scattered consignees. The chances are very great, therefore, that the commercial trucking companies could offer a less expensive service because of their ability to carry good-sized loads on frequent schedules. Their ability to do this, of course, is based upon service to a large number of shippers.

The paper makes a statement that fuel oil, referred to by Mr. Conway, can be unloaded without reheating. Mr. Conway indicates that this is possible, however, only in the summer months, but that at other times of the year reheating is necessary. He describes an interesting arrangement by which the steam for heating can be turned on and the unloading started simultaneously. This gives practically the same effect as if sufficient heat could be retained during the trip for unloading, as is possible during the summer months.

Economics of the Electric Truck in Delivery Service

By H. L. FORMAN,[1] MOUNT VERNON, N. Y.

THE electric truck is a vehicle of specialized application. It can be used most advantageously under the following conditions:

1 A fleet operation.

2 In congested areas where speed is automatically limited by traffic conditions.

3 On regular fixed routes of limited mileage.

4 By established companies which can foretell with reasonable certainty that the delivery conditions of their business will remain approximately constant, and which therefore are justified in the initial investment, purchase of charging equipment, etc.

In this specialized field the modern electric has definitely proved its economic value. An analysis indicating its proper application and comparative operating costs against other types of equipment shows these to be based on inherent physical and mechanical characteristics. Before discussing these, however, it would seem essential to define the standard of cost comparisons.

Transportation costs may be kept accurately and elaborately, and yet be vague and meaningless for interpreting truck economic values. This is because truck costs are usually expressed in terms of "cost per mile" or "cost per package." Both these accepted "yardsticks" of truck working values are unreliable. For example: Two trucks both deliver 1000 lb. of bread. Truck 1 travels 10 miles a day at a cost of 20 cents a mile; truck 2 covers a 40-mile route at a cost of 15 cents a mile; but when truck 2 is put on the route of truck 1, the cost becomes 30 cents a mile. Obviously, cost per mile becomes meaningless as an index for determining comparative truck economies. Similarly, cost per package is equally uninformative. Two identical milk trucks deliver their loads within the same mileage. Truck 1, because of the distance between stops and the class of trade served, might deliver half as many bottles as truck 2. Delivery cost per package would wrongly show that, with these identical trucks, one costs twice as much to operate as the other.

It is fundamental that the only sound basis for determining comparative vehicle economies is that of doing the same work under the same conditions.

Bearing in mind the specialized field of electric-truck application and the index by which economic values are compared a summary of many different users' statistics indicates the following electric-truck advantages:

1 *Flexibility of Chassis Construction Which Permits a Special Body Designed for Maximum Driver Efficiency.* A large user of all kinds of delivery equipment in New York, referring to his electric fleet, says: "Adaptability of chassis and body design is by far the most important consideration, because the difference in operating costs between vehicles is negligible compared with the cost of the driver's time in delivering goods."

2 *Suitability of the Electric to Operate in Congested Areas.* The same operator summarizes these features as follows:

(*a*) The driver is freed from mechanical worries, as all he

[1] Vice-President, Ward Motor Vehicle Company.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

can do is to move one lever forward and backward for ahead or reverse, and to apply a brake. This is against 12 separate movements in going from low to high gear on a gas truck, in which three levers or pedals operated synchronously by one hand and two feet are used for every traffic and delivery stop. (The starting and stopping of the motor is in addition to these movements.)

(*b*) The mechanism of the electric is not affected by weather conditions. It has no carburetor to adjust, or lubricants to be changed, or water-cooling system to protect.

(*c*) When it is considered that the entire power plant of the electric is almost identical with the self-starter superimposed on the gasoline engine, its comparative simplicity is apparent.

(*d*) The horse and wagon occupies 65 per cent more space and the gas truck about 30 per cent more space on the street than the electric of same capacity. This means better parking facilities, shorter turning radius, and easier manipulation in traffic.

There is, incidentally, a recognized public economic benefit from these factors, as well as other physical characteristics of the electric such as cleanness, odorlessness, and quietness. Simplicity, lesser liability to accident, and fewer road breakdowns mean greater reliability and a smaller number of reserve delivery units.

3 *Housing Economic Advantages.* The fact that the electric requires about 25 per cent less garage space than the gas truck and approximately 50 per cent less floor area than the horse and wagon is a vital cost consideration where real estate values are high. A recent example of this point was furnished where condemnation proceedings eliminated one of two buildings, both of which were necessary previously to house the total horse and automotive equipment. It was found that the smaller space occupied by the electric enabled the entire housing to be done in the remaining building. Furthermore, the company's architect pointed out that, due to the selection of the electric rather than gas equipment, no expensive building alterations were necessary.

4 *Advantageous Electric Insurance Rates.* Replying to a query on this subject by a large truck user, their insurance broker wrote as follows: "On liability and property damage, casualty underwriters allow a 25 per cent discount from gasoline-automobile rates. Fire insurance is not necessary, but even if it is carried it will be 50 per cent less than the gas truck. Fire insurance on buildings used for garage purposes varies as follows: Ordinary and fireproof buildings 50 per cent less; auto-sprinklers, 20 per cent less; fireproof auto-sprinklers, 15 per cent less. Theft rates are 75 per cent less than gas."

5 *Accuracy With Which Electric Truck Costs Can Be Budgeted.* There are fewer variable cost factors with electrics. Its chassis life is indeterminate, but proved to be from 10 to 20 years. Tire costs are less due to limited speed with more gradual application of power, and they can be predicted accurately on the basis of tire guarantees. Electric current for charging is computed on a fixed-contract-price basis that is, constantly decreasing throughout the country, is less liable to driver waste, and may be estimated closely on a yearly mileage basis. Battery costs, because of definite life guarantees, can be set up as a fixed item of cost. The only variable of expense is that of mechanical maintenance. In this connection the number of wearing parts of the electric chassis is so limited and the replacement and repair records on these are so comprehensive that they can be approximated within extremely narrow limits. An example of the accuracy with which operating costs can be budgeted was furnished by a large concern in the South. Before the purchase of a fleet of 90 electrics, detailed estimated operating costs were set up. At the end of three years the annual audits showed that the actual realized figures varied less than 1 per cent from predictions.

Simplified Comparative Operating Accounting. The easiest direct comparison of depreciation and maintenance costs can be made by eliminating from consideration all items common to both the gas and the electric truck. This means disregarding bodies, wheels, tires, frames, axles, springs, steering mechanisms, brakes, shop equipment, etc. (Such an arbitrary cancellation discriminates against the electric, because its limited vibrationless speed directly lessens upkeep and increases life on all parts.) There is now left all that differs—the two motive systems. With the electric, this is the storage battery and electric motor. With the gas truck, this is the engine, cooling system, starting-lighting-ignition system, fuel system, clutch, and transmission. On the battery and motor, the annual depreciation and maintenance is a fixed known sum, depending on the size of the unit. It is a figure, in general, that will vary from 30 to 50 per cent less than similar items of maintenance and depreciation on equivalent gasoline units.

Throughout this entire analysis, specific cost figures have been avoided. Such figures are relative; they involve many unknown and variable factors; and they seldom express comparable values. Instead, it is sound and logical to go behind the figures to the underlying facts which govern figures. Summarizing these facts, the economic place of the electric depend upon:

1 Its adaptability for delivery efficiency
2 Its suitability for operation in congested areas
3 Housing (garage) advantages
4 Lower insurance rates
5 Definite, predetermined, less-variable costs
6 Lower maintenance and depreciation.

Therefore, bearing in mind every phase of the limitations of proper electric-truck application, and aware of the only criterion by which delivery economies can be measured (cost per same work done), one can analytically determine where and how the economic advantages of the electric vehicle in delivery must be realized.

Economics of the Electric Street Truck

By L. A. DeMORE,[1] CHICAGO, ILL.

FOR general business purposes in metropolitan districts the motor truck has practically replaced all former horse-and-wagon installations and is now the chief means of merchandise transportation. True, there are yet in service a relatively small number of horse-drawn units, but these remaining few are feeling the pressure of specialized motor units, which will undoubtedly finish the horse-replacement program.

Two general types of motor trucks are in common use, each with its own peculiar advantages and fields of service—namely, electric trucks and gasoline trucks. The question of proper selection of the type of truck is very important if the operation of the business is to be conducted along lines of strict economy.

It is the purpose of this paper to deal with the characteristics and economics of the electric truck. At the start, there are admitted to be three outstanding limitations to the general use of electric trucks, namely:

1 *Limited Cruising Mileage.* The electric truck, deriving

[1] Assistant to General Sales Manager, Walker Vehicle Company.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

its power solely from a storage battery, is limited in the cruising mileage by the amount of energy contained in the battery. Under certain conditions two sets of interchangeable batteries can be used, which will enable the truck to be kept in 24-hour operation, and the limitation of mileage will be removed. However, this is only practical where the truck is in frequent touch with its home base. Interchangeable batteries are in daily use by a number of companies, among whom may be mentioned the Railway Express Agency and the Curtis Publishing Company.

2 *Limited Speed.* The maximum speed of the electric truck is built into it by the manufacturer and cannot be easily altered by the operator. What this speed is in miles per hour is largely determined by the work to be done. Electric trucks are in operation at speeds varying from 22 miles per hour on light- and medium-duty trucks down to 10 miles per hour on the heaviest trucks. Some variation in speed can be provided by the manufacturer to meet certain conditions. The variation usually

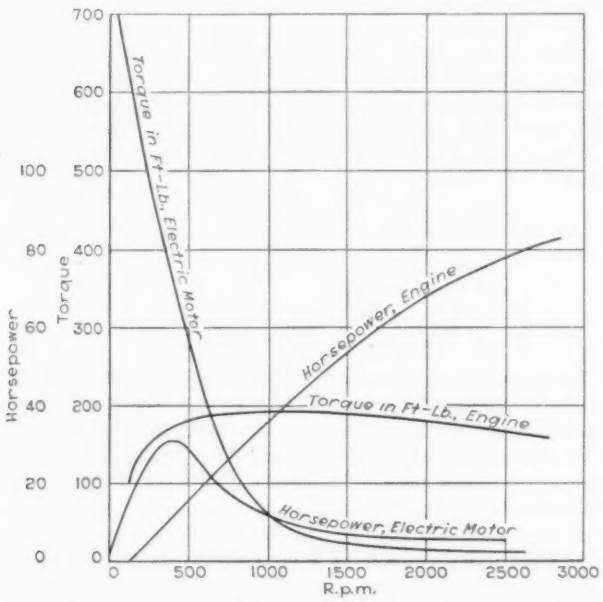

FIG. 1 CURVES SHOWING TORQUE AND HORSEPOWER OF A MODERN AUTOMOTIVE ENGINE AND AN ELECTRIC-TRUCK MOTOR

is accomplished by increasing the number of cells of the battery. This limitation of speed is ofttimes a tremendous selling advantage, as well as of particular economic value to the user, as it is the direct cause of lower insurance rates due to lessened accident hazard, lower maintenance, and longer economical life on account of decreased wear and tear. On such work as city routes, making hundreds of stops per day in a limited area, high speed is of absolutely no value. On the other hand, due to there being no clutch or transmission to operate and having an inherent fast pick-up, the electric truck on such work and in traffic congestion will actually maintain a higher average speed than is possible with other types of equipment, and part of its economy is due to such time saved.

3 *High First Cost.* To the average intelligent business man this should not be a limitation, but due to the fact that so few concerns keep anywhere nearly accurate costs of operation, the item of first cost is ofttimes given considerable weight, and the item of lower operating costs is thereby not made the deciding factor in the selection of the type of equipment. Many times a prospect will make the statement that it is all right for a larger successful electric-truck user to buy electric trucks because it has a lot of money. He does not appreciate the fact that the reason for the success of the larger company is most likely due to its keeping accurate records by which it determines its policies. The purchase of high-priced equipment is not because the company happens to have plenty of money, but because it knows that money is made only by using the best and most economical tools available in the business, irrespective of first cost, whether these tools be manufacturing machines, motor trucks, office machines, or any other equipment necessary to the business.

So much for the apparent limitations. What effect have they on the proper field of operation of the electric truck?

Let us accept the limitation of cruising mileage as that of one average battery. The limitation then means that a day's work must be accomplished within a daily mileage of, approximately, 45 to 50 miles on a $^3/_4$- to 1-ton truck down to a daily mileage of, approximately, 35 to 40 miles on a 5- to $7^1/_2$-ton truck. Such a limitation leaves as suitable work for the electric truck any route operating in a restricted area, in congested traffic, or having many stops. Among these, the most numerous are as follows:

1 Retail milk-delivery routes
2 Wholesale milk-delivery routes
3 Retail house-to-house bakers' routes
4 Wholesale store-delivery bakers' routes
5 Laundry routes
6 Retail ice-delivery routes
7 Wholesale ice-delivery routes
8 Department-store parcel-delivery routes
9 Department-store warehouse to substation deliveries
10 Chain-store deliveries.

In addition, the electric is also economically suited for:

11 Inter-plant haulage
12 Freight-station haulage
13 General urban express and trucking work
14 In general, any work now being done by the few remaining horse-drawn units.

Considering the foregoing as the legitimate field for the use of the electric truck, what, then, are the economies of operation which it will effect? In order to appreciate them, let us first have a simple picture of what the electric truck is.

Mounted under a pressed-steel frame is a conventional front axle with its springs, bearings, and wheels; also, a rear axle with its springs, bearings, and wheels. In its simplest form the truck has within this rear unit an electric motor and reducing gears which take the driving power to the wheels. The foregoing elements include all of the running parts in the truck.

To complete the vehicle a battery is slung below, in a compartment which serves to truss the frame; a controller is installed for manually regulating the flow of current from the battery to the motor; conventional steering and braking devices are added.

Now we have an electric truck; its simplicity is apparent. The motor is permanently connected, through gears of fixed ratio, to the wheels. When the truck is at rest, the motor is at rest.

Now, with this picture, let us look to the economies which result, and which are as follows:

1 *Low Depreciation.* The present-day electric truck should maintain economical service for not less than 15 years. When we assure that our company has a large number of trucks in operation today that are 15 years old or older, and weight is given to the improved designs, material, and methods which go to make up the present-day vehicle, one can appreciate that the economical life of the electric is practically indefinite. For accounting purposes, electric trucks are usually depreciated

over a 10-year life, which is certainly conservative. This 10-year life will usually represent an average of less than 100,000 miles.

2 *Low Maintenance.* Being so simply constructed, with few moving parts and with ample factor of safety from a load-carrying standpoint, very little labor or renewal of parts is required to maintain an electric truck. One man will easily do all maintenance and repair, except washing, on a fleet of as many as 35 electrics and still not be rushed for time.

3 *Low Insurance Costs.* There is practically no fire or theft hazard in the electric truck, and this is reflected in the underwriters' rates on fire and theft insurance. The average rate is about 50 cents per $100 valuation on 80 per cent valuation, and the rate does not increase with age of truck. Also, due to ease of control and safe maximum speed, there is a very low accident hazard, and this also is reflected in public-liability and property-damage insurance, the rates being 25 to 33⅓ per cent lower than for the corresponding size of gas truck.

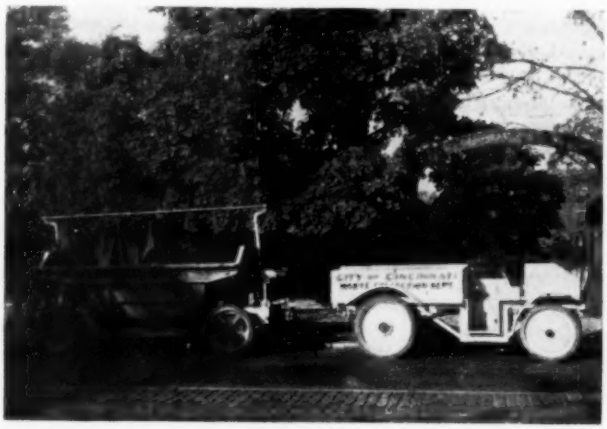

FIG. 2 ELECTRIC TRACTOR WITH TRAILER USED IN MUNICIPAL WORK

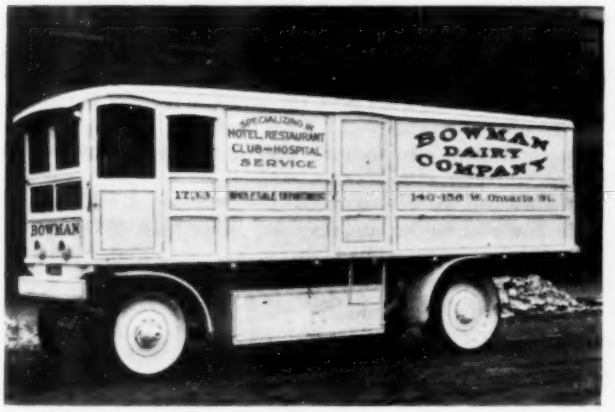

FIG. 3 ELECTRIC VEHICLE FOR WHOLESALE DELIVERY

4 *Garaging Cost.* The electric truck is no fire hazard in buildings. It can be garaged and charged inside of warehouses or manufacturing plants without affecting the insurance rate on the building or its contents. This means that enclosed loading platforms are often utilized for garaging, and the expense of separate garage buildings is saved.

5 *Cost of Current.* Current for charging the storage batteries is usually consumed on off-peak night rates, and current so obtained is very cheap. At 1 cent per kw-hr., current costs will vary from ½ cent per mile on light-duty electrics to a maximum of 2 cents per mile on heavy-duty electrics. Usually the cost of current plus the depreciation charge for batteries will be less than the cost for gas and oil on a corresponding size of gas truck doing the same amount of work.

6 *Fewer Accidents.* The underwriters' preferential rate on electric-truck insurance is based on actual experience of electric-truck users in the matter of few accidents. Aside from the saving in truck insurance premiums, freedom from accidents means reduced workmen's compensation, reduced maintenance, reduced time of equipment out of service, and reduced pieces of extra equipment.

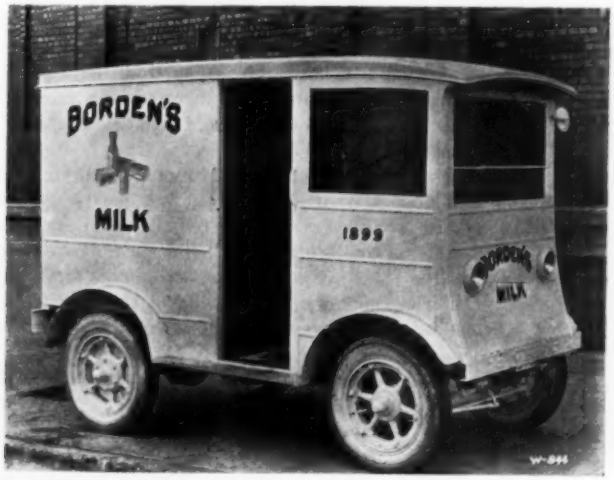

FIG. 4 ELECTRIC VEHICLE FOR "NOISELESS MILK" DELIVERY

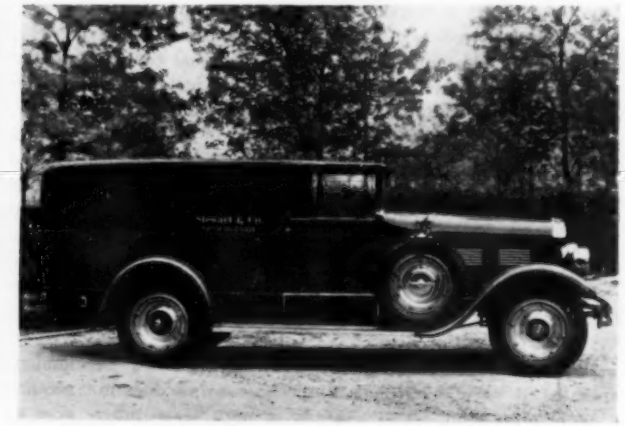

FIG. 5 ELECTRIC PACKAGE VAN WITH THE SMARTNESS OF GASOLINE-CAR APPEARANCE

7 *Dependability.* Dependability is essential for economical route operation. Dependability, also, demands the ability to operate under extremes of weather conditions. Aside from accident, it is extremely rare for an electric to be off its route, except for painting. This company has a large number of trucks operating which have not missed a day off their routes from one year's end to the next.

8 *Power.* From the standpoint of power, the electric is much more powerful than is a corresponding size of gas truck. Electrics will pull up grades or plow through snow where other equipment cannot operate. This great power does not come from a high-powered motor, but rather from the characteristics

of the motor. Straight-series motors are generally used in electric trucks. This type of motor develops its maximum torque at the stalling point of the motor. This is almost exactly the opposite of a gas engine, which develops its maximum torque only at high speed and therefore needs a gear reducer (transmission) to enable the engine to have enough speed to generate enough power to start a heavy load. Where the gasoline truck has to start its load through a transmission and by slipping a clutch, the electric motor, being always permanently connected with the rear wheels, starts the wheels directly the motor starts, and hence there is no shock on the mechanism.

9 *Few Moving Parts.* The motor armature, the gears, and the wheels are the only moving parts in the electric-truck drive. Add to this the steering gear and controller, and all the wearing parts have been named. The fact that there are few moving, wearing parts makes for low maintenance and high dependability.

10 *No Idling Mechanism.* When the electric truck is stopped, all parts are at rest. There is no idling motor consuming fuel and wearing itself out. Wear and tear on the electric occurs only when the truck is in motion and then to only a slight degree.

11 *Vibrationless.* The driving power, being a steady running rotating force rather than a reciprocating force, does not tend to set up vibration in the truck. The effect of this lack of vibration is evidenced in low maintenance and in the improved stamina of the driver.

12 *Noiseless.* The electric truck is absolutely noiseless in operation. For the many lines of business that specialize in night-time or early morning deliveries, this is a very valuable feature in promoting customers' good-will.

13 *Fast in Traffic.* Due to having no clutch or transmission to operate, the electric truck gets away faster from each stop and gets through congested traffic faster than any other vehicle. This time saved is worth money if intelligently used.

14 *Short Wheelbase.* The electric truck has, approximately, a 3-ft. shorter wheelbase than the conventional gas truck of the same size for any given length body. This feature saves garage space and makes for easier maneuvering and parking.

15 *Immunity to Weather.* The test of any equipment is not its fair-weather operation, but its operation in adverse weather conditions. Neither the hottest summer weather nor the coldest winter weather has any detrimental effect on the electric truck. The electric can be left out in below-zero weather for hours with no freezing or injury to any part. This immunity to weather conditions works for more dependable operation and does away with all expenses caused to other equipment by winter operation.

16 *Operating Temperature.* The electric-truck mechanism operates at normal outdoor temperatures and does not require a cooling medium. The absence of high temperature goes to prolong the life of the equipment.

17 *Sanitation.* The electric truck is clean and sanitary. There are no odors or fumes—an important consideration, particularly in the delivery of food products, clothing, and other mechanism. The drivers can easily keep themselves neat and will always convey to customers the impression of scrupulous cleanliness which their employers want customers to have.

18 *Simplicity of Operation.* No special skill is required to operate the electric truck other than to steer the vehicle. The speed of the vehicle is controlled by one handle operating a controller, which regulates the flow current from the battery to the motor. Because a skilled operator is not necessary, route men, who are usually salesmen, can be selected for their selling ability rather than their truck-operating ability. This means better route men and more sales for the owner.

19 *Driver Satisfaction.* The modern electric-truck driver is a satisfied driver. Not being subjected to excess noise, vibration, or wear and tear on their nerves due to high speed; not being called upon to tinker with complicated dirty mechanisms; being able to keep clean; not being worried about the performance of their truck—all have a decided bearing on the driver morale and driver turnover. Any reduction in driver-salesman turnover is a big saving to the owner.

20 *Special Designs.* Due to the electric units being so self-contained and simple in design, the electric truck lends itself readily to special designs to fit any type of business. These special designs result in savings beyond that possible with conventional-design vehicles.

21 *Advertising Value.* The electric will maintain its new appearance over its practical life as compared to the very short time a gas truck will retain its new appearance. This is due to the lack of vibration and racking due to high speed; also, to the absence of gas and oil spray attendant on gas-truck operations. On the street, clean, well-painted, and noiseless, it creates an impression of confidence for the company whose name it bears, in the minds of people who see it. Being continually on the move, the electric truck is a better advertising medium than a billboard on a boulevard, and this advertising value is worth a great deal to its owner in establishing prestige.

22 *Comparison of Operating Costs of Electric Trucks Versus Gasoline Trucks.* In their general uses, no direct comparisons are usually possible. The gasoline truck is generally conceded to be very expensive to maintain in short-haul work with a high number of stops per mile, due to the wear and tear of starting and stopping. This high-maintenance cost for multistop work has resulted in many concerns still using horses because of their objection of paying a high first cost for electrics. On the other hand, the electric does not compete with the gasoline truck in long-haul work. In general, it will be found true that the electric truck, properly applied to its work, will be the most economical means of transporting merchandise as compared to all other types of street equipment, and as compared to gasoline-truck costs in the electric-truck field, the saving in favor of the electric will be always greater than 25 per cent.

In conclusion, electric-truck operation may be summed up in one sentence, as follows:

The electric truck, immune to the extremes of cold or heat, more powerful for its size than any other type of equipment, easily controlled, sturdily built, with a simplified mechanism of few moving parts, avoids costly maintenance, practically never wears out, keeps merchandise and material flowing smoothly on schedule time, and effects important savings for its owner.

Economics of Highway Trailers and Semi-Trailers

By W. G. RETZLAFF,[1] DETROIT, MICH.

THE past few years has been an extensive development in motorized freight transportation. Traffic men have recognized the motor truck as one of their best tools in the handling of freight. In the minds of many, there exists the thought that the truck may some day displace the railroad, especially in the shorter hauls not exceeding a 300-mile radius.

This has resulted in the establishment of corporations to haul freight between large cities. The truck companies, seeing the possibilities, have designed trucks or tractors especially adapted for long-distance freight hauling.

Legislation has followed, and today practically every state has laws regulating the length, width, speed, and weight of vehicles on the highway.

As the motor-transport business continued to grow, some men specialized in this field. Later, these men became known as transportation engineers. And today we find that practically every large truck and trailer company has established a transportation engineering department whose chief function is to determine the most economical method of handling any particular commodity using truck-tractors with trailers.

Surveys are made, and from the data collected, the most eco-

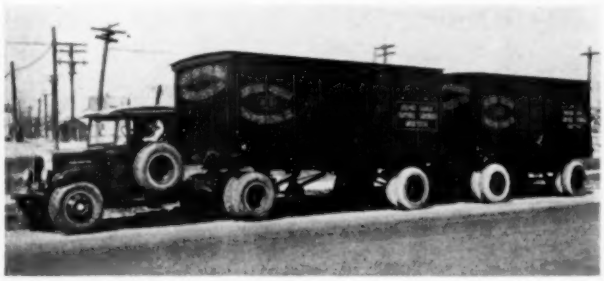

FIG. 1 SEMI-TRAILER AND FOUR-WHEEL TRAILER HAULING ABOUT 20 TONS PAY LOAD ON MICHIGAN HIGHWAYS

(The Southern Michigan Transportation Company, formerly the Michigan United Electric Railway, has turned loss into profit by eliminating electric freight cars and substituting 83 trailers.)

FIG. 2 SOUTHWESTERN TRANSPORTATION COMPANY HAULING THROUGH THE SOUTHWEST FOR THE COTTON BELT RAILROAD

(They are using a large fleet of semi-trailers and four-wheel trailers.)

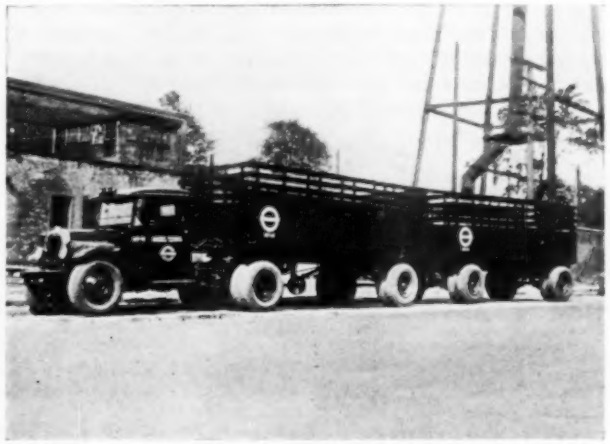

FIG. 3 EASTERN MICHIGAN TRUCKING COMPANY, FORMERLY THE DETROIT UNITED RAILWAY

(They are eliminating electric cars and substituting the tractor-trailer method of freight hauling.)

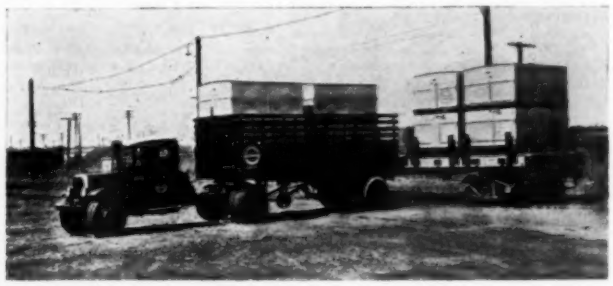

FIG. 4 EASTERN MICHIGAN TRANSPORTATION COMPANY SYSTEM USING THE CONTAINER METHOD

(The electric railway hauls the containers between the points far apart, and the containers are then shifted to the trailers for pick-up and delivery. These containers weigh about 2500 lb. apiece, but new design will not exceed 1500 lb. The capacity of each container is about 5 tons.)

Tractor includes chassis and cab only. Truck and body includes cab and body value, about $500 on 2-ton and up.

To obtain total daily operating cost for tractor-truck or for a truck with a body, multiply the variable charges per mile by the number of miles traveled per day and add the fixed charges per day. No overhead is included.

nomical vehicle and the operating cost can be predetermined. The operators soon found that the single overloaded truck could not be operated on the highways on a paying basis. The tonnage was not large enough, and the cost was too great. Legislation also interfered.

Necessity being the mother of invention, the trailer was evolved and adopted. And today we find the motor truck used as a locomotive pulling trailers over the highway, hauling large loads cheaper than ever before.

Cost of Operation

The most important question that the transportation engineer must answer is, "What are the possible savings and how soon will the installation pay for itself?" To answer this it is first necessary to determine the approximate operating cost.

Data on truck-tractor and trailer operations have been compiled from the various surveys made and in collaboration with several of the truck companies. These have been placed in table form, and the approximate operating cost can be easily determined.

The operating costs have been divided into two divisions—first, the daily fixed charges, including such items as interest, insurance, garage, license, and wages; and second, the variable charges, including gasoline, lubricants, tires, depreciation, and maintenance. The variable charge is based on a mile of operation. The tables herewith contain all cost data to determine the total operating costs.

TABLE 6 FOUR-WHEEL TRAILER VARIABLE CHARGES (IN DOLLARS)

Model	A-431-R	B-461-R	B-473-R	B-479-R
Gasoline (additional used by truck)	0.006	0.007	0.008	0.01
Lubricants	0.003	0.0035	0.004	0.005
Tires (20,000 miles on pneumatic and 10,000 on solids)	0.0076	0.0152	0.0285	0.042
Depreciation (200,000 miles, less tires)	0.0058	0.006	0.0082	0.0094
Maintenance	0.0029	0.003	0.0041	0.0047
Total, per mile	0.0253	0.0347	0.0528	0.0711

To obtain total daily operating cost for four-wheel trailer, multiply the variable per mile charge by the number of miles travelled per day and add to the daily fixed charge. No overhead is included.

For example, suppose that in the state of Ohio the engineer is recommending a heavy-duty 3½-ton tractor truck to pull a 7½-ton semi-trailer carrying 10 tons and a four-wheel trailer 7½-ton capacity also carrying 10 tons. Assume that it is a 100-mile run, or a 200-mile round trip. To determine the total cost add the fixed charge of the tractor truck, or $7.02 (Table 1), to that of the semi-trailer, or $1.039 (Table 3), plus that of the four-wheel trailer, which is $1.21 (Table 5), for a total of $9.27. The variable cost will be:

For the tractor (from Table 2)	$0.1450
For the semi-trailer (Table 4)	0.0465
For the four-wheel (Table 6)	0.0711
Total per mile	$0.2626

Total variable cost for 200 miles—$52.52.

The total operating cost will be:

Fixed charge	$ 9.27
Variable cost	52.52
To haul 20 tons	$61.79

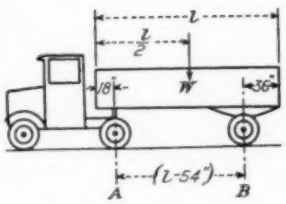
or a cost of $3.09 per ton or $0.154 per cwt., which is actually less than the present railroad rate.

The saving in time is also a factor. In the truck-trailer, shipment from Detroit to Chicago, delivery is guaranteed within 24 hours, whereas railroad shipment requires three to four days.

Equipment to Recommend

The transportation engineer is faced with the various state laws and the physical limitations of the equipment. Is it best to recommend a long-wheelbase truck with a four-wheel trailer, or the tractor-truck with a semi-trailer, or the tractor-truck with a semi- and four-wheel trailer?

Generally speaking, the four-wheel trailer, although it carries the load equally distributed, is rather hard to handle in heavy traffic. From depot to depot and for long-distance hauls it serves its purpose.



The semi-trailer, however, is easily handled in the most crowded traffic and will double the truck load because the weight is spread over two axles. However, the semi-trailer should be so constructed that the body overhangs in front of the tractor axle and throws about 45 per cent of the pay load on the tractor axle. This will give about the same gross load on the trailer and tractor tires and permit using the same size of tires all around.

Weight Distribution

To determine the weight distribution of a semi-trailer and tractor, note the illustration:

$$\text{Weight at } A = \left(\frac{\frac{l}{2} - 36 \text{ in.}}{l - 54 \text{ in.}}\right) W + (0.20)\, C + \text{weight of rear end of tractor}$$

$$\text{Weight at } B = \left(\frac{\frac{l}{2}L - 18 \text{ in.}}{l - 54 \text{ in.}}\right) W + (0.80)\, C$$

Let

l = length of trailer in inches

W = pay load plus weight of body

C = weight of chassis.

Length of Combination of Vehicles

Most states limit the operator to two trailers, and in some states only one trailer is permissible. The overall length of a combination of vehicles permitted varies in most states between 60 to 85 ft. The average tractor and semi-tractor will have an overall length of about 38 ft. If a four-wheel trailer is added behind the semi-trailer, the overall length becomes 56 ft.

Fig. 5 Universal Carloading & Distributing Company Delivering Containers From Railroad Yard to Consignee

(Each tractor-trailer can haul three containers, whereas the truck carries only two containers.)

Fig. 6 One of the Trailers Used in Shifting Freight Between Depots in Minneapolis and St. Paul

Axle Loads

Most states limit the gross load to 16,000 or 18,000 lb. per axle and a few to a 5000- or 6000-lb. wheel load. The value of the trailer can be readily seen. With an 18,000-lb. axle law, the semi-trailer could carry 36,000 lb. gross on the tractor rear axle and on the trailer axle. The four-wheel trailer can also weigh a gross of 36,000 lb. In a few states the total gross load is also limited; for example, in New Jersey the limit is 30,000 lb. gross and one trailer only.

Tires

When one considers that on every vehicle the average tire cost is about 2 cents per mile, the importance of this item is apparent. The pneumatic tire is gradually replacing the slow-speed solid tire, and there is hardly a doubt that in the near future the balloon tire will occupy the same position in the hauling of freight as it does today in the passenger-car field. Most operators must be cautioned that pneumatic tires cannot be overloaded in the same proportion as solid tires. The ratings of the tire manufacturers should be followed in all installations.

Fig. 7 Trailer Train as Used by the E. H. Scott Transportation Company

(They own a large fleet of Trailers and haul most of the freight for the Pennsylvania Railroad.)

Fig. 8 Trailers of the Middle States Transit Company, Owned by the Ohio Northern Electric Railway Company

(They are extending freight service beyond the track limits, using the trailer method. These units are duplicates of those used by the Southern Michigan and Eastern Michigan Transportation Companies, and the equipment is built to interchange with the Michigan companies.)

Truck Tractor

The old saying that a horse can pull more than it can carry is also true in modern truck transportation. On the average, a 5-ton semi-trailer calls for a $2^1/_2$-ton tractor or a 10-ton semi-trailer calls for a 5-ton tractor. In other words, the capacity of the tractor should be one-half of the rated capacity of the semi-trailer.

Trucks vary to a great extent in both the horsepower of the motor and in the rear-axle gear ratio. Both are very important, depending on the grades of the route, the total load, and the speed.

Experiments have shown that 12 lb. of rim pull at the tractor wheels will pull 1000 lb. gross weight on a level paved road, using a rubber-tired Timken-bearing-equipped vehicle. For average operating conditions, a 2 per cent grade is assumed. In other words, it requires 32 lb. of rim pull to move 1000 lb. gross weight on a 2 per cent grade.

Knowing the torque developed by the engine (generally given

by all truck manufactures), the rim pull can be easily determined from the following formula:

$$RP = \frac{T \times 12 \times R \times E}{\frac{D}{2}}$$

Where

RP = Rim pull in pounds
T = Torque in foot-pounds
R = Rear-Axle gear Ratio
E = Mechanical efficiency about 90 per cent
D = Nominal Tire diameter

For example, take the G.M.C. tractor T-60, about a $3^1/_2$-ton capacity, with 38×9.75 balloon tires and with a maximum axle-gear ratio of 12. The torque is given by their Engineering Department as 215 ft-lb. Substituting in the formula, this becomes

$$RP = \frac{215 \times 12 \times 12 \times 0.90}{\frac{38}{2}} = 1466.5 \text{ lb.}$$

On a 2 per cent grade it will move $1466.5/32 = 45.8 \times 1000$ lb. = 45,800 lb. gross in high gear.

As the tractor and trailer weight about 14,000 lb., the maximum pay load would be about 31,800 lb.

Speed

Knowing the governed speed of the motor, which in the foregoing example is about 2500 r.p.m., and the tire diameter and axle-gear ratio, the maximum speed can be easily calculated.

By changing the axle-gear ratio, of which every manufacturer provides several, the best compromise between pay load and speed can be arrived at.

Lowest Cost Freight Transportation

In the average industrial plant today the factory and the office have been organized and placed on a systematic basis by the modern mechanical and efficiency engineer. Unfortunately, most of the them stop their efforts at the shipping-room door. The Shipping Department, which handles all incoming and outgoing material, is generally regarded as a necessary evil—an overhead item of little account—and the operation and choice of equipment are left largely to the judgment of the shipping clerk. As a result, large savings are possible in almost every plant where a survey is made. It is not at all unusual to find an installation which will pay for itself in a year's operation.

The large corporations have awakened to this situation, and realizing the savings, they have appointed able executives in charge of their rolling equipment.

It is believed that the day of the heavy, slow-moving, solid-tired, inefficient truck is past. It is being rapidly replaced by the more efficient, high-speed six-cylinder pneumatic-tired truck manufactured on a quantity basis and adopted from the passenger-car field. This light truck, used as a tractor and coupled with a semi-trailer, is ideal for industrial and city work. In Table 7 a comparison is made between a 3-ton truck and a good six-cylinder, $1^1/_2$-ton tractor with a 3-ton semi-trailer.

TABLE 7 COST COMPARISON FOR 3-TON TO 5-TON LOADS

	Using a 3-ton truck	Using a $1^1/_2$ ton tractor with 3-ton semi-trailer	Savings in using semi-trailer
Maximum capacity	5 tons	5 tons	...
Daily fixed charges	$7.41	$6.67	$0.74
Variable operating cost, per mile	0.15	0.082	0.068
Total cost per 50-mile day	14.91	10.77	4.14
Total cost per 15,000-mile year	4473.00	3231.00	1242.00
Initial cost of investment	3750.00	1890.00	1860.00

Notice the savings of $1242 per year and that the investment of $1890 will pay for itself in about one and one-half years.

Another popular size for city work is the 5-to-$7^1/_2$-ton unit. In Table 8 a comparison is made between a 5-ton truck and a 5-ton semi-trailer coupled to a $2^1/_2$-ton tractor.

TABLE 8 COST COMPARISON FOR 5-TON TO $7^1/_2$-TON LOADS

	Using a good 5-ton truck	Using a good 6-cylinder, $2^1/_2$-ton tractor with a 5-ton trailer	Savings in using semi-trailer
Maximum capacity	$7^1/_2$ tons	$7^1/_2$ tons	...
Daily fixed charges	$8.70	$7.98	$0.72
Variable operating costs, per mile	0.2565	0.142	0.115
Total cost per 50-mile day	21.52	15.08	6.44
Total cost per 15,000-mile year	6456.00	4524.00	1932.00
Initial cost or investment	5800.00	5101.00	790.00
Additional equipment included	Cab and $500 body	$500 body with B. K. vacuum power brake	

Notice the savings of $1932 per year over the straight truck method. It might be added that these figures were actually proved by the Standard Oil Company and the National Refining Company, which have decided to replace all their 3-ton and 5-ton trucks with the lighter tractor and semi-trailer. These units operate on grades as high as 17 per cent.

Undoubtedly it is the cheapest freight transportation today.

MH-52-10

Placing Wet Concrete With Belt Conveyors

By E. L. BENSON,[1] AURORA, ILL.

In this paper the author tells of various construction jobs where belt conveyors have been used successfully for placing the wet concrete. Figures are given to show the economies of belt-conveyor use for such purposes, and the particular types that best meet specific conditions. There are a number of things that must be given consideration in the design of conveyors for handling wet concrete. The author tells how special conditions are met.

APPLICATION of belt conveyors to wet-concrete building brings to building construction the economies and efficiency of one of the oldest yet most reliable units in the material-handling field. The constant feed of the conveyors forces the men in forms to work faster and permits the mixer to be operated at top speed continuously.

Portable conveyors for this work must be light so that they can be moved easily, and at the same time be strong enough to withstand heavy loading. They must also be dependable, as the contractor's season is short and, consequently, it is necessary to work at peak load under severe usage for the entire season. All of these facts must be considered in designing suitable equipment. The practicability of using conveyors for handling wet concrete was realized early and the design of portable conveyors was changed to meet conditions peculiar to the handling of this material.

The first use to any extent of conveyors on a major project was to handle and place concrete on a branch-sewer job at Springfield, Ill., seven years ago. A portable mixer fed a portable conveyor direct, which placed the concrete in the forms. At this time the application was comparatively new and, consequently, was watched closely. But even at this early date, the concrete was poured successfully, cutting down the gang from 27 to 10 men, eliminating all wet-batch wheelers, three dry-batch wheelers, and all track layers.

Another early major project in which conveyors were used was the pouring of the Seventh Street Viaduct in Decatur, Ill. A portable mixer fed a 66-ft. portable conveyor which elevated the concrete, placing it into forms at a height of 34 ft. There were 60 pier bents in line about 40 ft. apart. The forms were set up just ahead of the mixer and conveyor. Consequently, these units moved from one form to the next without interruption. The reinforcing steel in the pier bents was only $^3/_4$ in. from the surface, which made a wet plastic mix desirable. A $1 : 1^1/_2 : 2$ mix, with 1-in. stone as the maximum, was used, giving the concrete a $5^1/_2$-in. slump; a pliable, flowing, easily worked mixture. The conveyor handled this mixture at an average angle of about 31 deg. with no trouble from spillage, and a finish of even texture was produced.

Similar equipment has been used for pouring open channels.

Fig. 1

Fig. 2

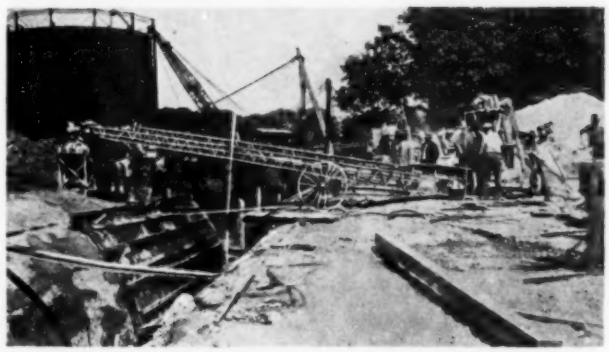


Fig. 3

FIGS. 1, 2, AND 3 PLACING CONCRETE ON LARGE SEWER AT SPRINGFIELD, ILLINOIS

After the excavation of dirt has been completed to grade, forms are placed ready to receive concrete. A portable mixer and a conveyor are used, both units traveling parallel to the right-of-way. On the Los Angeles flood-control project in Glendale,

---

[1] Conveyor Division, Barber-Greene Co. Mr. Benson was born in Batavia, Ill., May, 1896. He entered the University of Illinois Civil Engineering College in 1915. He saw service for fifteen months overseas with the A.E.F. Mr. Benson received the B.S. degree in Civil Engineering from the University of Illinois in 1922. He entered employ of the Barber-Greene Company Engineering-Sales Department in 1923 and served as manager of the Field Service Department for two years, being placed in charge of the Conveyor and Special Applications Division Department in 1929.

Presented at the Third National Materials Handling Meeting, Chicago, Ill., March 5 to 7, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Cal., a 30-ft. portable conveyor and paver eliminated all wheelbarrows, cars, chutes, hoists, etc. Two units poured and placed 45 tons of concrete per hour. The conveyor carried the concrete from mixer to forms so rapidly that 6 to 8 men were kept busy on top of the form tamping. The work consisted of a concrete-lined channel 3400 ft. long, 47½ ft. wide, with 8 ft. perpendicular walls reinforced throughout. Concrete was poured at the rate of about 75 ft. of wall per hour and the entire job was completed in 32 working days.

FIG. 4 CONVEYOR AND MIXER USED ON CONSTRUCTION AT SPRINGFIELD, ILLINOIS

FIG. 5 PORTABLE CONVEYOR DELIVERING CONCRETE FOR SEVENTH AVENUE VIADUCT, DECATUR, ILLINOIS

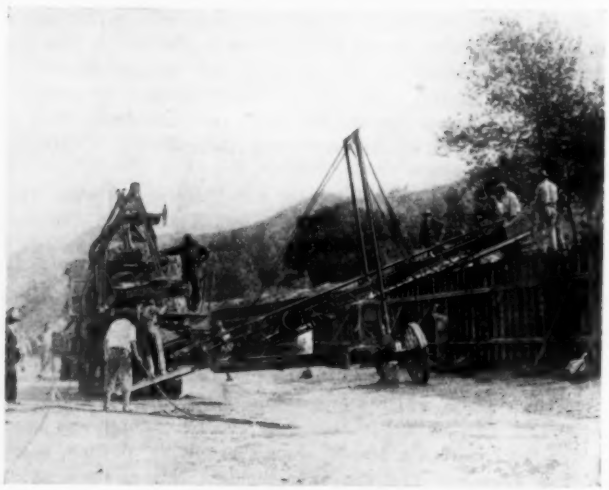

FIG. 6 PORTABLE CONVEYOR DELIVERING CONCRETE INTO SIDE-WALLS OF OPEN CHANNEL

Another type of construction, where conveyors have played an important part, is the stupendous and complicated sewage-disposal plants. These plants are becoming a necessity to the welfare and health of highly congested areas. An elaborate belt-conveyor system was installed for pouring the concrete in a large sewage-disposal plant located on the west side of Chicago. Conveyors were used to handle dry aggregates as well as concrete. There were 150,000 cu. yd. of concrete poured, and conveyors handled the major portion of this for pouring groups of units comprising skimming tanks, grit chambers, screens, and sludge-drying beds. A central mixing plant was used and concrete was fed direct from the mixer to a short conveyor which fed a permanent conveyor, 500 ft. long, equipped with self-propelled tripper. The permanent conveyor extended the entire length of the concreting area, feeding into shorter portable units at right angles which traveled over supporting runways and placed the concrete.

Conveyors also have been used extensively in placing concrete in retaining-wall forms on railroad work and deep-waterway projects. In this type of work the conveyors handle from 40 to 60 cu. yd. of concrete per hour, speeding up the jobs materially, due to the ease with which the units can be moved, which is essential for this type of construction.

There are two other fields of concrete construction which hardly have been touched upon; namely, the use of conveyors

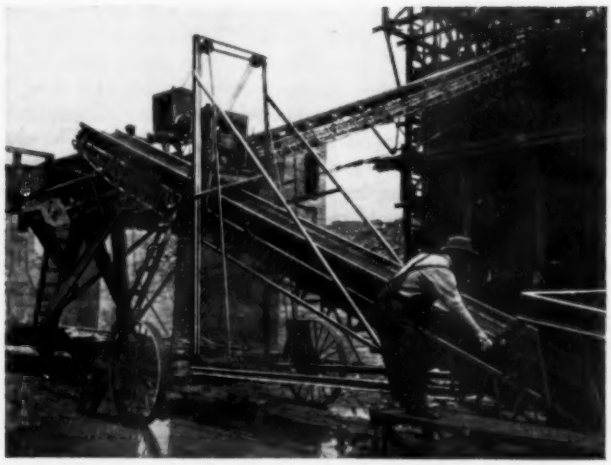

FIG. 11 TWO CONVEYORS DELIVERING CONCRETE TO FORMS

for pouring large dams such as are built in the far West and for pouring large buildings. As to the former, few data are available, but one project will be explained to give an idea of the procedure.

The Skagit River dam, located in Washington, is used for impounding the water supply of a number of cities in that state. It is approximately 1000 ft. long, 375 ft. high, and 170 ft. at the base. It is mass concrete construction, and the engineers specified that, in placing, the concrete could not be dropped a greater distance than 5 ft. This practically eliminated any other system than that of conveyors. Several towers were used with a skip hoist for elevating the concrete from the mixer. This part of the equipment is identical to the well-known spout and tower system. A boom was also supported by the tower from which two con-

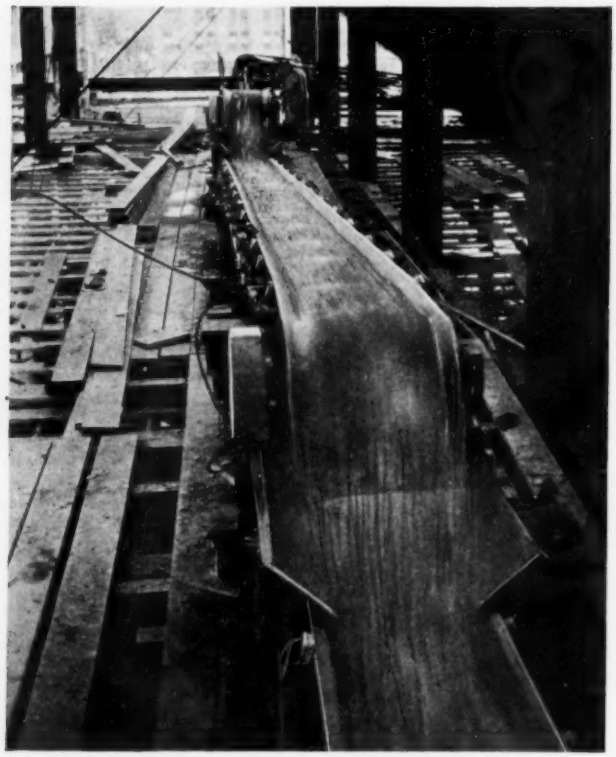

FIG. 12 DELIVERING CONCRETE FROM ONE MACHINE TO ANOTHER

veyors were suspended The boom unit, including the conveyors, was constructed so that it could be raised or lowered the entire height of the tower, and in addition the second conveyor was made to swivel so that a large area could be served.

On the new Merchandise Mart building, located in Chicago, which is the largest building of its kind in the world, 55 conveyors were used to handle the dry aggregates and wet concrete. The dry aggregate was brought in by battleship hopper-bottom cars. The tracks were located directly beneath the building itself, and the unloading section of track was excavated below so that the material flowed by gravity to the conveyor hoppers in pits. There were six belt conveyors used for unloading the aggregate, four on stone and two on sand. These machines unloaded 30 cars of material a day.

Two tunnel belt conveyors under the sand storage and two under the stone brought the material to two central mixing plants, one located at the side of the buiilding and one in the center. The material was then elevated by means of bucket elevators to the batching bins above the mixers.

Each mixing plant had two one-yard mixers. The concrete was elevated from the four mixers by four towers, having one-yard buckets, to a point two stories above the floor being poured. The short portable belt conveyors were located one floor above the floor being poured. Assuming that the third floor was being poured, the buckets in the towers raised the wet concrete to the fifth floor where it was discharged by a trip to a one-yard hopper. The hopper had a chute in the bottom which carried the mate-

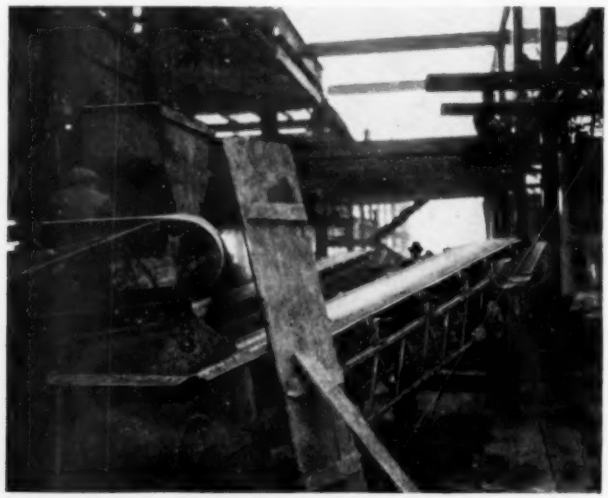

FIG. 13 STEEL IS ERECTED IMMEDIATELY ABOVE CONVEYORS, MAKING A VERY FLEXIBLE SYSTEM

rial down to the waiting conveyor on the fourth floor. Altogether, there were 44 portable conveyors handling concrete from this point. These units were 40 ft. long and each was mounted on rubber-tired castors. In distributing the concrete from the towers from 1 to 15 of these conveyors were used as required to reach the point above the spot being poured. The machines were moved about very easily, forming combinations, sometimes involving complicated crooks and turns.

Each conveyor was constructed in two units so as to facilitate easier handling when being hoisted from one floor to the next. The conveyors worked in series, and, as the placing of concrete progressed, the conveyors farthest from the hoisting towers were removed and put in position ready to go on the floor above.

To give some idea of the magnitude of the job and apparent successful application of conveyors for pouring the concrete, some figures will be given. The building was approximately 700 ft. long, 400 ft. wide and 18 stories high, with tower extending to 25 stories. There were 142,000 cu. yd. of concrete poured. To break this down further, so that it is more comprehensible, 6000 cars of gravel, 4000 cars of sand, and 1000 cars of cement constituted the material to pour this amount of concrete. About an acre per day of concrete was placed, and six days were required to complete a floor. The actual pouring of concrete started in March and was to continue through November but, due to a change in design, the job was held up 7 weeks, so that the pouring of concrete extended through December. When construction was temporarily stopped, the conveyors were used to handle debris of all kinds. This is important to a contractor, in that with conveyors he has equipment which is not limited in its usage.

From experience based on furnishing conveyors for handling wet concrete on jobs under varied conditions, it is found that there are a number of things which should be taken into consideration in the design of conveyors used for this purpose.

In general, when handling concrete and where conditions

permit, it is best to use a series of short units instead of long ones. Short units have a tendency to keep the concrete mixed and turned over as it discharges from one unit to the other. This also eliminates any tendency to segregate. In this connection it is important to space carriers as close as possible so that the belt will span the distance between carriers without sagging too much, due to the weight of the concrete.

Wet concrete is handled at angles varying from 12 to 36 deg. The angle at which concrete can be elevated is directly proportional to the slump of concrete and shape of the aggregate. The drier the concrete the greater the angle that the conveyor will handle the material. If the coarse aggregate is large and round, the angle cannot be as steep. Likewise, the capacity of a belt conveyor is affected by the slump of concrete, the shape of the aggregate, the angle of inclination, and belt width. The belt speed can be increased to 300 ft. per min. to increase the capacity. Beyond this speed, considerable slippage will occur with a consequent added wear on the belt. A belt is recommended not less than 24 in. wide because it has been noticed that anything less will cause spillage.

A rubber conveyor belt should be used which is not affected by water and in addition is easily cleaned. The best grade of belt is desirable, with at least five plies—or more, depending on the length of the conveyor. It should have a $^1/_8$-in. or $^3/_{16}$-in. extra rubber cover on the carrying side. The belt should also be heavy so as to decrease the sag between carriers as much as possible, yet it must be pliable so as to trough with the shape of the carriers to prevent spillage.

The power for driving the conveyor is directly proportional to the weight per cubic foot of the concrete, which, of course, is greater than that of either sand or gravel.

A machine to handle concrete must be light so that it can be moved readily and at the same time be constructed so that it will have strength to withstand the heavy loads which, in some cases, develop stresses of considerable magnitude. Conveyors of the portable type having Warren-type side trusses laterally braced seem to be the best suited. They combine maximum strength with minimum weight.

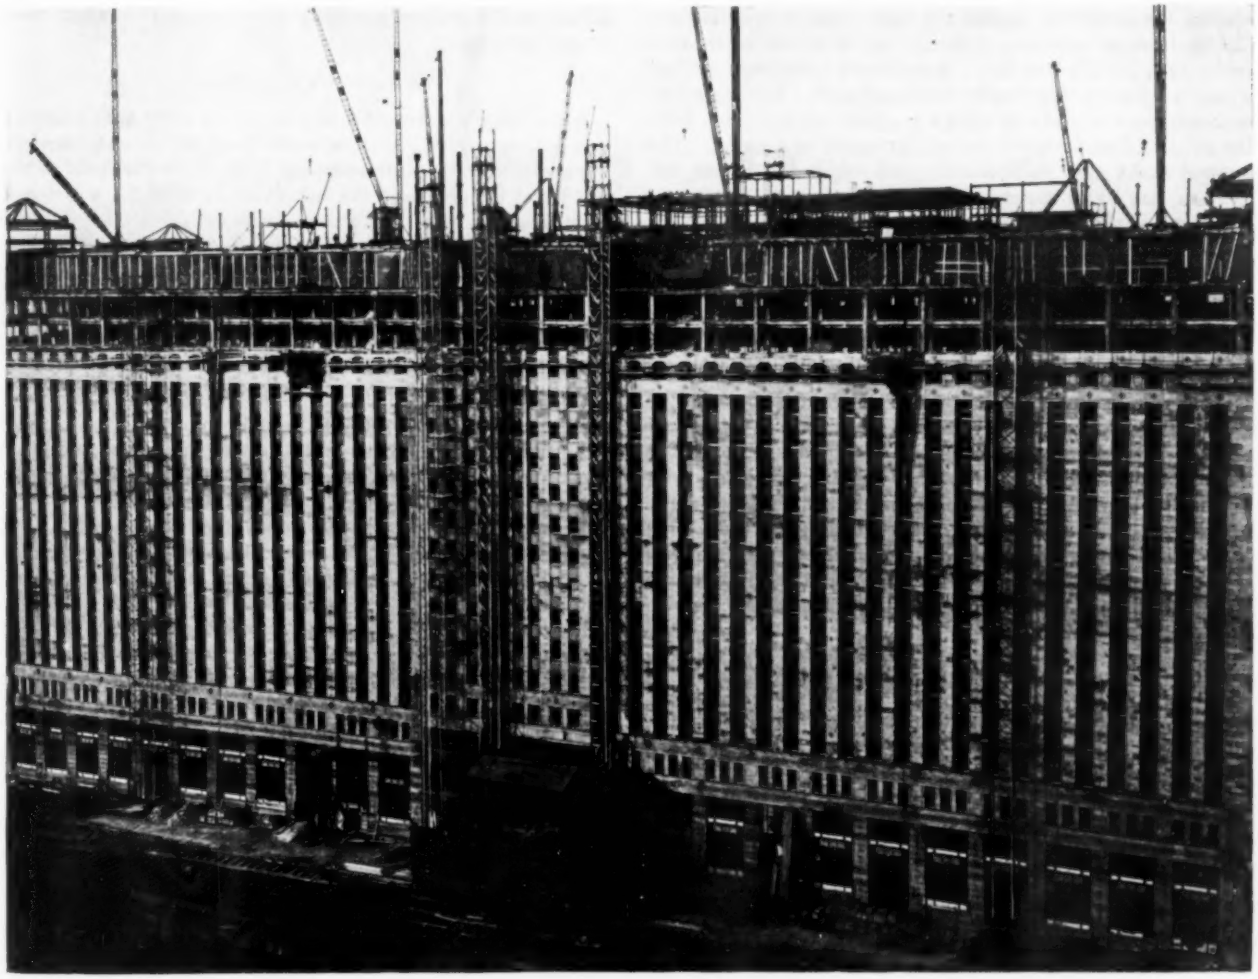

FIG. 14 PROGRESSIVE CONSTRUCTION OF BUILDING

Placing of rollers approximately 2 ft. apart eliminates the sag of the belt between rollers and, consequently, decreases the possibilities of segregation of aggregates. Where possible, it is desirable to use a feeding hopper for feeding the concrete onto the belt of the conveyor. Such a hopper assures a constant and uniform feed of the material on the belt, and, at the same time, starts the material off in the center of the belt which is desirable. The foot end of the conveyor should have a concentrating hopper about 9 in. wide so that a thin narrow ribbon of concrete is conveyed. The conveyor should be built as open as possible, expec-

ially at the foot end, where often there is spillage. This will make it easily accessible for cleaning. It is advisable to clean the conveyor thoroughly after each day's run. It is often desirable to coat the frame and all steel parts with oil which prevents concrete from setting on the frame and makes it easier to remove. An increased size for the tail pulley so as to eliminate undue flexure of the belt produces a saving in belt wear. It is also necessary to make this portion of the conveyor heavy and rugged to withstand the load of the wet concrete when dumped in the hopper. It is necessary to furnish rubber or wood scrapers at the discharge pulley located just under the pulley to clean the return run of the belt. On jobs where spillage is not of extreme importance, use is made of a counterweighted scraper, the weights keeping the scaper up against the belt. This scraper is satisfactory in most instances, although not as senstitive as other types. By this is meant that if once thrown away from the belt, it does not immediately replace itself against it. It is, therefore, necessary on some jobs to design a spring scraper which holds the scraping element up to the belt by means of a spring. This scraper works very satisfactorily and wipes the return belt clean so that very little material is carried back. The material to be used as the wiping medium also in some cases is important. Usually two or three thicknesses of belt would suffice while in other cases a 1 in. thickness of sponge rubber is furnished which does an exceedingly good job.

The conveyor as a medium for placing concrete has proved entirely satisfactory from a practical as well as economical standpoint. The length of the unit is limited only by conditions on the job or due to limitations of the drive. The action of the concrete while going over the rolls and the expansion and contraction of the belt between rollers keep it in continuous motion. This mixes the ingredients more thoroughly and, consequently, produces a better-mixed concrete than when it first leaves the mixer.

The principle of handling wet concrete is the same as that used for conveying any other material, using certain refinements in design to meet the conditions involved, bearing in mind that the machine will receive the severest usage and still must operate without break-downs.

Discussion

W. W. Burden.[2] Where freedom from shut-downs is as necessary as it is on engineering construction jobs, it would seem important to use special care in the selection or design of the troughing idlers on this type of portable conveyor unit. The value of dependable idlers and good bearings is important, expecially when conveyor speeds are increased. The bearings would necessarily have to be amply protected against the ingress of both dirt and moisture and should be designed so that lubrication is a simple operation and one that is easily handled by ordinary construction labor. It would also be interesting to check up on the actual depreciation of troughing idlers used in portable equipment of this type.

G. F. Pfeiffer.[3] To prevent spillage from return belts, revolving brushes and scrapers have been used, but complete spillage and a gradual gumming up of the parts has not been entirely prevented.

Author's Closure

In handling wet concrete, as well as any other bulk material, over belt conveyors, it is important to have well-designed carriers. For portable belts or semi-portable belts where the speed of the belt is not too great and the belt width 24 to 30 in., a cast-iron plain bearing with, preferably, pressure lubrication is best adapted from a practical and economic viewpoint. The bearings should be dust and grit proof to eliminate wear. The carriers should be the three-roll type, with rollers about 4 in. in diameter.

For high-speed belts, heavy loads, long conveyors, and where a saving in lubrication is important, a carrier having roller bearings and slightly larger diameter rollers is essential.

Protection against moisture in the bearings is of secondary importance, because on a well-designed conveyor there is practically no spillage, and the return-belt scraper wipes the return run of the belt dry; consequently, no water comes in contact with the carriers.

From experience it has developed that the squeegee type return-belt wiper is the most practical and gives perfect results. A double squeegee on spring-steel arms, fulcrumed at the end with adjusting screw in the middle of the spring arms, is believed to be the best type. It is positive in action, and the scraping elements are held in contact with the belt at all times. The scraping element made up of 4-in. seven-ply transmission belt is preferable. This has the required stiffness and flexibility to wipe the belt clean without injuring it.

Material Handling in Production of Pork Products

By A. W. DeVOUT,[1] CHICAGO, ILL.

This paper describes the various operations through which hogs pass from the buying pens in the stockyards until the various products are dressed, boxed, and placed in refrigerator cars ready for shipment. Handling equipment plays an important part in speeding up the operations, lowering costs, and doing away with heavy manual handling.

ONE OF THE pioneers in applying mass production to a continuous-line operation was the meat packer. His equipment was simple; an overhead rail and a shackle with which the carcass of the animal was hung by its hind feet. This shackle was pushed along the rail by a man with a long pole from operator to operator. A power-driven chain conveyor with a finger attachment soon eliminated this man, and this increased production and lowered the cost. Since that time there has been a steady increase in material-handling equipment of all kinds in every department of the meat-packing plant.

The packing industry is essentially opposite in procedure to many industries, such as the automotive, which assemble their many raw materials for the manufacture of one variety of product. The meat packer must dismember one raw material, the live stock, and produce almost innumerable varieties of goods. It is worthy of notice that these two differing types of industries use practically the same handling equipment, perhaps slightly altered to fit particular needs. In the packing industry this equipment has been so adapted and so coordinated with the rest of the plant that a practically continuous flow is maintained from the buying pens to the coolers and from the cutting rooms to the shipping docks.

The pork department, although but one of the many departments in a packing plant, offers the best illustration of coordination among the various types of handling equipment which are typical of the packing industry. The following description shows the flow of materials in the pork division of the Chicago plant of Swift & Co. This flow of materials is illustrated by the diagrammatic sketch, Fig. 1.

From the buying pens in the stockyards the hogs are driven up ramps to the top floor of the hog house. The elevating of live stock by means of ramps is economical, and hence gravity chutes and conveyors are extensively employed in later operations for transferring the product from floor to floor and department to department. On the top floor rest pens are provided where the hogs are washed and held for killing. Driven next to a pen in the dispatching room, one hind foot is shackled to the rim of a large revolving wheel which in turning raises the pendent hog to an overhead rail. The shackle engages with the overhead rail and automatically releases itself from the revolving wheel. By gravity the hog slides down the rail to the sticker, who skilfully severs the main veins and arteries of the neck. From the sticking rail the hogs then slide down to the bleeding rail. There ample time is allowed for bleeding. The hog is then allowed to drop into the scalding vat by a loosening of the shackle. The empty shackles are returned by a gravity rail to the shackling pen.

[1] Engineer, Swift & Co., Union Stock Yards. Mr. DeVout was born in Harrisburg, Pa., Aug. 3, 1898. He received his degree as Mechanical Engineer from Lehigh University in 1919. After graduation he was employed by the Corn Products Refinery Company at their Argo and Kansas City plants, specializing in the steam and power departments. In 1926 he entered the employ of Swift & Co. in the office of the Supervising Engineer, giving particular attention to the operations of boiler and engine rooms of their produce plants and to the developments of new machines and methods for the handling of poultry and eggs and for the manufacture of butter.

Presented at the National Materials Handling Meeting, Chicago, Ill., March 5 to 7, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the scalding vat. This chain drag has displaced the old method of propelling the hogs through the tank by means of poles, and what is more important, insures that every hog remain in the scalding vat the proper length of time. This prevents over- or under-scalding. The purpose of scalding is to dissolve some of the protein substances which surround the hair in the hair follicles and make it possible to remove the hair easily.

FIG. 2 HOGS IN REST PENS

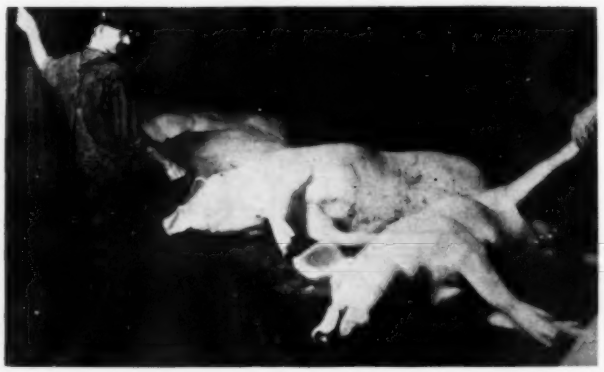

FIG. 3 GAMBRELING TABLE—A GAMBREL STICK IS INSERTED IN THE TENDONS OF THE HIND LEGS TO SPREAD THEM FOR THE DRESSING OPERATIONS

Another chain conveyor takes the hog through the dehairing machine from which in a few minutes the hog drops out on to a moving slat conveyor. Here a gambrel stick is inserted in the tendons of the hind legs to spread them for the dressing operations. The hog, fastened to the gambrel stick, is then hung on a trolley. From this point onward to the coolers the hog is carried on an overhead rail by this trolley. The hook which was used to bring the hog to the gambreling table, after removal, is returned by a rail to the front end of the scalding vat.

On the hog-dressing floor, directly above the rail, there travels a chain conveyor with a finger about every 27 in. These fingers engage each trolley so that the hogs proceed forward at regularly spaced intervals. The chain conveyors on the dressing floor are driven through variable-speed reducers which accommodate the killing grates. The fact that maximum capacity of this floor is 750 hogs per hour results in a chain-speed of approximately 27 ft. per min. The average hog capacity is about 400 per hour.

The hogs are admitted to the dressing operations by a man called the feeder, who also removes the hind toes. The hair not removed by the machine is removed by men that are stationed along the dressing line. However, to insure a perfect job, the hogs pass through a singeing machine and is then washed. Still being moved by the conveyor the hogs come to the header, who cut the heads free, yet leaving them to hang by a small piece of skin so that the government inspectors may examine the throat glands, marking and tagging those which do not meet the government requirements.

The carcass is next opened so that the viscera can be removed. The viscera on removal is placed on a moving table that is divided into pans. Each pan on this table is synchronized with a finger on the conveyor chain, so that the viscera proceeds forward at the same speed as does the hog from which it was removed. The purpose of this parallelism is to allow the government inspectors sufficient time to inspect the viscera and to tag those animals not up to federal specifications. Now, after evisceration, the hogs move along to scales at the end of the first conveyor chain. Here in drafts of five each the hogs are weighed. At this point the hogs are fed by a slightly inclined rail from the scales to the second chain conveyor. Such operations as splitting, removal of the head, leaf-lard removal,

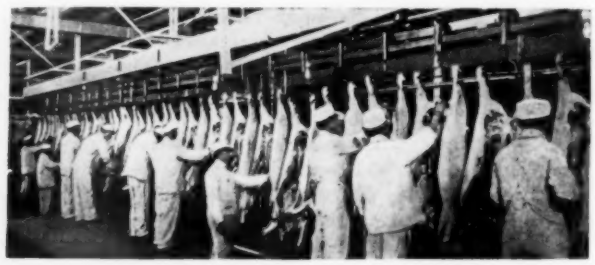

FIG. 4 HOG DRESSING—CHAIN CONVEYORS WITH FINGER ATTACHMENTS MOVE THE HOGS THROUGH THE DRESSING OPERATIONS

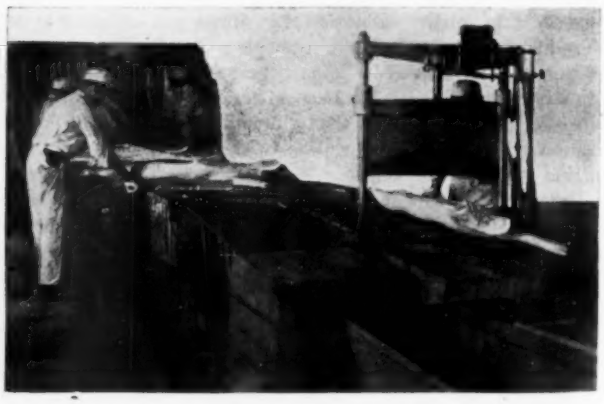

FIG. 5 REMOVING HAMS AND SHOULDERS FROM SIDES

and washing are completed on this second conveyor and the hog is ready for the coolers. Still remaining on the overhead rail, however, the hogs are conveyed by another series of chain conveyors to the coolers below. Each cooler is equipped with overhead rails so that the hogs may be spaced evenly throughout the rooms.

It is interesting to note that it requires only 25 min. for a hog to travel from the sticking pen to the coolers. After remaining in the coolers for 24 to 48 hr. the hogs are ready for cutting. They are moved from the coolers to a lift which brings them to the cutting floor. A chain conveyor pulls the hog across the moving slat conveyor and the tendons of the hind legs are cut,

dropping the hog on this moving table. The ham is scribed by a portable saw, and the next man deftly cuts off the ham, which drops by a chute to the ham-trimming table on the floor below. The next operation is the removal of the shoulder by means of a shoulder chopper similar to a guillotine. The shoulder is dropped by one chute and the side by another chute to the floor below.

As the sides reach the cutting table the loin is scribed with a portable electric saw and each side is slid along the table to a loin puller, who uses a drawknife for the operation. The loin is then passed to the trimming table, where it is trimmed and graded. It is then weighed and boxed on roller conveyors ready for delivery through a chute to the assembly conveyor. After the loin is pulled, the side is fed into a belly roller, which at the same time splits the side into a fat back and a belly. The fat back is trimmed and disappears down a chute to the floors below. The spareribs are removed from the belly by means of a drawknife, and the belly proceeds to the trimmers, antecedent to its removal to the curing cellars below.

On the same floor the hams which were removed on the floor above slide to the scene of the ham-trimming operations. Here a moving slat conveyor is used, and finally, at the end of the table,

Fig. 6 Interior of a Smoke House Showing Hams Hung on Special Trolleys

the hams are slid by a spiral chute conveyor to the grading room in the curing cellars.

It is worthy of notice at this point that the fresh product is boxed, weighed, and delivered on roller conveyors, and advanced to chutes which connect with the assembly conveyor on the third-floor cooler level.

Hams and bacon, after the curing process is completed, are taken from the cellar to soaking vats and chuted to slat-conveyor tables where they are prepared for smoking. As the product leaves the tables it is hung on special trolleys running on an overhead rail system that leads to the smokehouses. After the smoking, the trolleys are pushed to the smoked-meat hanging room there to await wrapping. The trolleys are dropped on a special lift to the wrapping room. Here is a series of belt conveyors and wrapping tables which discharge the wrapped product for packing into boxes. The boxes are carried forward by means of a belt-driven roller conveyor to a chute which discharges to the same assembly conveyor mentioned before.

In the packaging of sliced bacon the same familiar belt conveyor is used. The boxed product, ready for shipment, slides down a spiral chute to the head of the shipping conveyor on the tramway.

The assembly conveyor on the third-floor cooler level, as mentioned before, receives the fresh-pork packed orders and the smoked-meat packed orders through chutes. This conveyor, which is of the slat type, is connected by a gravity roller conveyor to another, a slat conveyor, which raises the packed goods to the tramway conveyor. At this point the boxed sliced-bacon slides on to the tramway conveyor.

Backed up against a rail which runs parallel to the shipping or tramway conveyor is a row of tractor trailors. In an aisle between this rail and the conveyor, the shippers stand removing from the conveyor the goods destined for their particular cars.

Fig. 7 Wrapping Hams and Bacon on a Table Equipped With a Belt Conveyor

Each man has assigned to him certain cars, and as each address on the package is marked with the car number, his work is quite simple. On this tramway the tractor trains are made up, and the tractors, now loaded, haul the product via the overhead tramways to a tractor train elevator which drops the entire train to a loading dock.

In this article only one assembly room is described, but other departments are also equipped with them, and they also are tied in with the tramway system. With the use of different assembly rooms in the various buildings, the overhead tramways, and five tractor train elevators, only a short space of time elapses before an order including items from many departments can be placed at the door of a refrigerator car.

Discussion

Nixon W. Elmer.[2] The paper covers a great deal of ground and, of course, could not go into detail. For instance, in the last part of the paper but a brief description is given of the efficient tractor trailer, assembly room, and train elevator system. Most of us do not appreciate how important a movement is involved. Figures for operation at the Armour plant may be of interest.

During 1929 there was shipped out of the Chicago packing plant one and one-half billion pounds of products and, on the average, each pound of this went for more than two journeys by tractor-trailer train. The cost per electric-tractor hour was almost exactly $1. However, before this is compared with the author's average figures, it should be noted that this includes the operator, the building maintenance, depreciation, and rent as well as maintenance and replacement of each tractor's individual share of over 4000 trailer trucks.

In analyzing individual tractor costs for both short and long hauls, it is interesting to find that they both worked out to almost the same cost, namely 1 cent per 1000 lb. per 100 ft.

[2] Engineer, Armour & Co., Union Stock Yards, Chicago, Ill.

While the figures are correct for departmental distribution of expense, they are, as abstract figures, not so favorable as they legitimately should be because of a plan used to encourage efficiency. The department is not charged for return loads. This makes the recorded tonnage too low and the ton-mile cost too high in like proportion, perhaps as much as 15 or 20 per cent.

MH-52-12

Hidden Costs in Materials Handling

By J. I. McCORMICK,[1] PITTSBURGH, PA.

A large variety of material-handling equipment and methods are used at the East Pittsburgh plant of the Westinghouse Electric and Manufacturing Company. The author tells how material is handled in different departments and the type of handling equipment found best suited to the requirements. He discusses various material-handling problems in a general way and tells of methods that are essential to reduce handling to a minimum.

INDUSTRY, in America today, holds its present position in the industrial world because it has adapted and applied mechanical conveyances, standardization, single-purpose machine tools, centralization of like products into one-plant set-ups where mass production has germinated, and grown plants that are a source of pride. With this progress ultimate customers are educated to accept a standard product, and engineering and sales policies are developed that have revolutionized industry. All this, along with the attitude of the workmen and their acceptance of the tools handed them, has made industry in America the envy of the world. Some of our keenest competitors in the world markets have adapted our approved methods. In Germany, Japan, or Italy today can be seen much of America's manufacturing procedures, and, in many instances, they have achieved higher success with our tools and methods than have we ourselves. Fundamentally, they start with an advantage in that their basic wage is some 50 per cent lower than ours. It behooves us if we wish to retain a balanced market here and abroad to dig deeper and better into those items that make up manufacturing costs.

Today no executive questions that a proportion of his unit costs is tied up in handling. The exact per cent varies in individual plants, but the author through association with some five plants, which have included automobile small parts and electrical apparatus, has accumulated sufficient data to say that approximately 80 per cent of the labor contents in unit costs is traceable to handling. Of this 80 per cent, 50 per cent is taken care of through operations on the floor, 12 per cent has to do with receiving, transferring to plant, transportation to the first operation, and packing and shipping; the remaining 18 per cent is a most fertile field for reducing unit costs, and one which presents problems that are answered and solved only after hard, diligent study.

A plant-planning engineer's job would be easy if all his layouts could be centered around quantity production, allowing mechanical handling and gaiting throughout, but unfortunately there are many plants, and many activities within plants, due to lack of production and certain inherent characteristics of the product itself, which do not lend themselves to any elaborate conception of materials handling and manufacturing processing, but reduced costs must be forthcoming under any system of manufacture. The cost trend must be established downward, and any plant of fair organization can lay out a new plant for a given product under ideal manufacturing conditions. When finished, this will be the last word in plant and manufacturing facilities. It takes a high-calibered plant organization, however, to take an old plant manned by 10- to 25-year old veterans, and swing them to new methods and turn out products at a unit cost comparable to the more fortunate competitor. This can be done, however, and within reasonable expenditures by judicious modernization.

The Westinghouse plant at East Pittsburgh is a diversified plant, manufacturing, in some form, a wide range of electrical apparatus. It covers approximately 5,000,000 sq. ft. of floor space scattered over a radius of eight miles, with six separate plants serving the main plant.

The foundry produces approximately 3,000,000 lb. of castings a month. The punch shop ships approximately 3,000,000 lb. of punched material. Shipments during 1929 averaged 11,200,000 lb. a month with an average of seven handling operations for each, which means that within the plant approximately 78,400,000 lb. are handled each month. Adding to this scrap ratio, there is coming in and handled through the plant approximately 42,336 tons. Manufacturing quantities average 50 to 100 pieces in the main items. This tonnage does not include coal, ashes, incoming maintenance material, or machine tools, which amount to approximately 70 cars a month.

Materials handling is a real problem to this company, and is placed by the management as of paramount importance throughout the East Pittsburgh plant. It is of such importance that two distinct departments have been formed for materials handling. The first is the transportation department, whose head C. A. Fike presented a paper at the spring meeting of the A.S.M.E. in 1928, at Pittsburgh. This department functions between plants and brings the bulk to the first operation on the floor, it also handles the semi-finished and finished product from department to department, but is not concerned with intra-departmental movement. The second is the plant-planning and layout department's function. This with the production department schedules and plans the material movement through to the shipping platform.

The objectives at East Pittsburgh through the materials-handling set-up and floor layout is to keep the work at one level, as it is found to cost $0.0036 for a floor lay-down and pick-up again to machine or bench level; also keeping the work in direct float and scheduled gait. Of course, these objectives are fundamentals in specialized plants, but are real problems when applied to the diversified plant.

It is planned to handle material mechanically as soon as it reaches the plant. In the punch shop the first machine is separated from the broad-gage track by a sliding door only, so that the sheet is unloaded directly to, and through the coating machine, ready for storage ahead of shearing. This eliminates one

---

[1] Superintendent, Plant Planning and Layout Department, Westinghouse Electric & Manufacturing Company, Pittsburgh, Pa. Mr. McCormick is a graduate of University of Pittsburgh. He was employed as field engineer for the Twin Falls North Side Land & Water Company for three years and served as superintendent of rate, layout, and production, for the Geimmer Manufacturing Company during 1913 and 1914. Other positions include those of assistant superintendent of manufacture for Continental Motor Co.; plant engineer for the Republic Motor Company; Captain, Motor Corps Division, A.E.F., in 1917 and 1918; district engineer, Pennsylvania State Highways Dept.; and field engineer, Duquesne Light Company.

Presented at the Third National Meeting of the Materials Handling Division, Chicago Ill., March 5 to 7, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

handling, or a movement of 3,000,000 lb. of sheet stock a month.

The product coming from the foundry is loaded into boxes that fit the inter-works transportation, either industrial gage or trailers. These boxes are placed at the run-off from the last cleaning operation. The inspector pushes the cleaned castings from his bench into the box, where they are piled on a broad-gage car for East Pittsburgh. The car is delivered at a point where an overhead crane will deposit the box of castings on an industrial car and lift truck or trailer for delivery to the first machine operation. The company is getting away, gradually, from in-

FIG. 7 MISCELLANEOUS CASTINGS SPRAY PAINTED WITH THE AID OF VERTICAL MOVEMENT OF TURN TABLE AND CONVEYOR FOR RETURN TO SECOND COAT

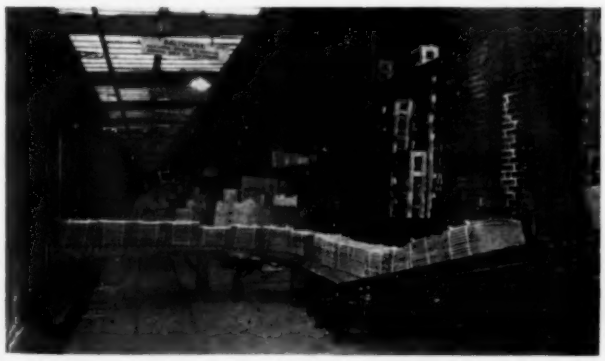

FIG. 8 GRAVITY AND POWER CONVEYOR MOVING CARTONS FROM CAR TO STORAGE

dustrial railway and lift trucks for the inter-works transportation by employing tractors and trailers. This means wider aisles, ramps, driveways, etc. throughout the plant. The economies that have been introduced more than justify the change-over. The saving is estimated at $33,000 a year under present plant loadings.

The correct answer to any handling problem is obtained through analysis of the factors involved in production:

1 Floor space available
2 Physical layout
3 Receipt and storage of raw material
4 Distribution of raw material and element parts
5 Classification of machine tools
6 Machine loading
7 Activity
8 Design
9 Separation of sub-assemblies
10 Separation of specials from standard
11 Scheduling
12 Complete assemblies
13 Processing
14 Inspection and testing
15 Physical properties
16 Storage of finished parts
17 Shipping
18 Investment
19 Economies.

Each of these factors usually presents different problems in handling, and when analyzed will give the desired method to use. Each factor must be treated separately and matched with the type of handling equipment best adapted to it. There are

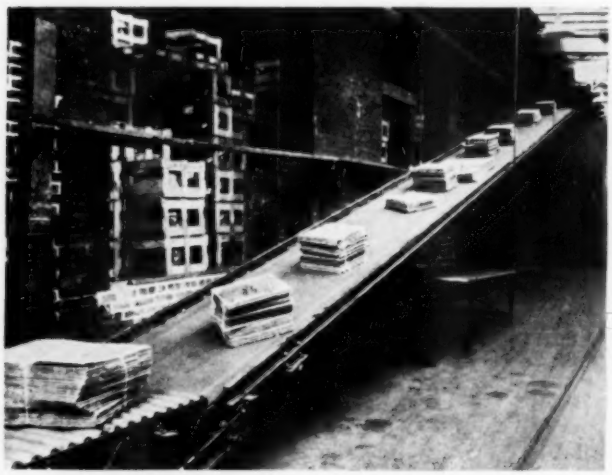

FIG. 9 CARTON CONVEYOR MOVING MATERIAL TO A SECOND LEVEL

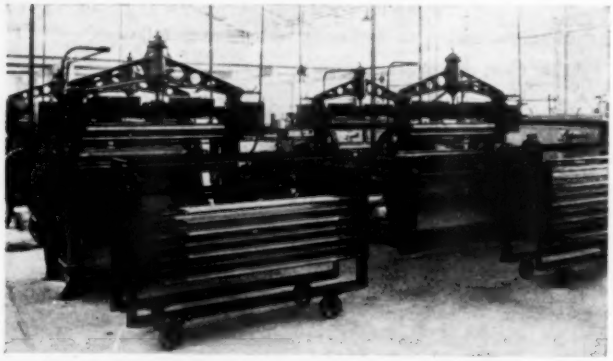

FIG. 10 BY PLACING MANDRELS ON TRUCKS FOR THE NEXT OPERATION OF BAKING, REHANDLING IS ELIMINATED

many factory managers and superintendents who still cannot see a place in their plant or department for mechanical-handling installations which they have seen elsewhere. It is not because these men are dull. Instruction on how to use equipment has been unmethodical and too fragmentary. The right application must be made of suitable, coordinated, material-handling equipment.

All have seen applications of handling equipment unsuitable, expensive, and nothing short of an "economical crime."

Those who have lived with reduced costs will recall that until recently handling was not considered in the analysis of those factors which made for profit or loss. The main points of consideration were material, major machine tools, tool fixtures, and design. Crude methods of machining, high cost of materials, and, above all, the design engineer, were criticized for the cumbersome designs with excessive weight and impractical tolerances and methods to obtain them. Engineering, and the art of manufacture, have advanced. Engineers have reduced weights and costs on large apparatus through fabrication, where every piece or order may be entirely different, involving no more waiting on patterns and castings.

All of the foregoing are factors in costs that are on the surface and which are obvious to those who look, but under the surface are hidden costs. These costs cannot be other than those of overhead, false economics, and handling.

Those factors which would give an algebraic expression for a handling constant, eliminating hidden costs, those intangible

FIG. 11 STATORS ARE HANDLED FROM MACHINE TO INSPECTOR BY CONVEYOR AND THEN TO INDUSTRIAL TRUCK

costs that are continually paring down profits and reducing the handling expression to its lowest terms are as follows:

A = Cost of handling from car to storage
B = Cost of handling from storage to first operation
C = Cost of handling from first operation, or manufacturing, to shipper.

Hidden factors involved:

X = Rehandling cost for "A"
Y = Rehandling cost for "B"
Z = Rehandling cost for "C"
W = Minimum handling costs

$$(A + B + C) + (X + Y + Z) = W$$

1 An outstanding hidden item difficult to measure is the handling cost of stock which does not have regular attendants; crews or individuals are shifted from other activities, periodically. Where one attendant is assigned to the entire section, modern handling facilities may not be considered justifiable, whereas, analysis may show that the operator is burdened with handling, and at times, several men are found helping the single attendant. Summarizing the time spent annually, it is found equivalent to two or more attendants. Therefore introduction of economics by modern handling facilities on surface costs are justified as full benefits will be realized only through reduced overhead where handling is an overhead factor.

2 *Broad-Gage Transportation.* This class of transportation, within and without, is most costly and should be avoided, if at all possible.

a Unloading Facilities for Raw Materials. Here is one place where rehandling must be eliminated and Babylonian methods abandoned. There are handling facilities on the market for individual problems.

b Where broad-gage transportation is essential, mixed cars

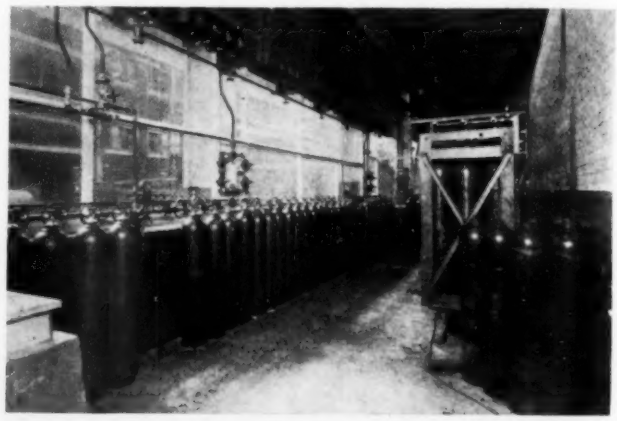

FIG. 12 HYDROGEN BOTTLES FOR FIELD USE ARE KEPT IN RACKS ON INDUSTRIAL CARS UNTIL FULLY CHARGED

should be avoided with material for north, east, west, and south parts of the shop.

c Tractors should be used for shifting in the yards, and power wenches for unloading positions, re-spotting empty and full cars to avoid idle-crew time and getting around Interstate Commerce full crews.

d Concrete should be used between broad-gage tracks to permit operation of tractors and trailers; particular attention should be paid to the area necessary for safe operation of tractors in bad weather.

With respect to broad-gage transportation, the time will be welcome when railroad companies will adopt standard cars to meet the handling problems. Possibly, a collapsible top for gondolas would be welcomed by those interested in steel, bar, sheet, pipe, and other materials. With the present box cars emptying costs are excessive.

3 *Power Plant.* This should be looked over, as there are innumerable handling problems, and ones which can go to the handling market for cure.

4 *Maintenance.* Here are involved many handling operations. The two most important ones are the "man" and "materials" movement. The man, or gang, should be given the right unit for conveying tools and materials to the job, preventing a pyramid of the "plumber's practice."

5 Handling also reverts back to the purchasing department. Its attention should be called to correct sizes required; eliminating handling of oversized stock and avoiding losses in scrap. Correct sized stock permits direct placement from car to floor, at the point of manufacture. This applies to sheet, sections, bar, and pipe stock.

6 *Scheduling.* There is considerable to be said about planning and scheduling raw material to the first operation on the floor, and keeping it in "float." Hardware should be located on the floor in the line of flow, thereby, eliminating rehandling.

7 *Manufacturing Level.* This term implies that materials

should be maintained at one level during the process of manufacture. It costs, as pointed out in a previous paragraph, much money to change levels, it increases man hours and investment in handling facilities. Modern machinery has played a great part in reducing the wear and tear on the human element, and correct methods of handling can do as much if given the same consideration and coordination of the shop forces. The operator should be kept at his position by moving materials to and from him by means of mechanical handling. The supervisor should have his set-up so arranged that he does the walking, and at a glance knows that the operator is kept in his position with work so scheduled that he has a visual measure of the day's production.

8 *Red Tape.* Red tape, or paper handling, is another source which, if not analyzed, will eat up reductions made through other sources. This set-up should run parallel with the manufacturing

FIG. 13 REDUCING HANDLING OF RESISTORS BY CONVEYORS—RAW MATERIAL IS KEPT IN CONTAINERS UNTIL USED

set-up; in other words, the clerk who is unproductive labor and a part of overhead should work in close connection with the paper work, following the material, and having it automatically returned to him so that he is rightly informed of the progress of the order. Systematic material routing is systematic paper routing and reduces to a minimum the necessary evil of stock chasers.

9 *Material Movement.* Movement through the manufacturing level should at all times be continuous. Skids should be used in connection with lift trucks, tractors, conveyors, portable tote-pan trucks, and racks. The skids should be designed with wheels so that they can be portable between immediate operations and still be handled by means of electric lift trucks or tractors for longer hauls. But, of all the handling methods and conveyances the simplest and most efficient method is termed "set-down" operation, or handling from operator to operator. Such set-ups have been accepted in preference to conveyors under certain circumstances.

Even with conveyor installation handling must be watched as often excessive handling on and off the conveyor, from operation to operation, is not shown in the operation itself. In a particular case there were 45 operators on a small unit weighing 10 lb. As this unit was handled off and on the belt each time, a close analysis revealed that a saving of 0.0003 hr. per operation could be effected or 0.0009 hr. per unit by direct passing. With the activity of 5000 units a day, the net savings were 45 hr., or the equivalent of $5^5/_8$ operators.

10 Inspectors should be kept moving.

11 *Processing.* This should be kept in flow and be timed so that refinishing is not necessary, nor wrap-up for protection.

12 Set-ups should be watched for break-ups. A production man may be "sandwiching in" his mistake, making rehandling necessary.

13 Handling must be tied-in so that the time-study department will have a clean-cut breakdown of handling operations. Intermediate handling operations should become a part of the operation line-up.

14 Americans are known as wasters both in industry and in their homes. They have been branded with the quotation that "their garbage cans would feed Chnia." Handling of materials must be done with the utmost conservation of materials and labor in mind. Excess material on castings should be watched. It costs to handle extra poundage both as castings and turnings. Salvage of scrap should be watched and that department centralized, transportation and physical handling should be saved allowing for improved control and studied work-over of scrap. Handling of hardware should be watched and standard containers used from receipt to the point of application, eliminating physical handling in and out of binnage, and in transportation. Processing should be watched. Centralizing will aid in obtaining manufacturing quantities to justify conveyorized set-ups, increase man output, machine loading, and improve the product.

15 The management of the Westinghouse Company has been most liberal in applying the incentive wage plan to activities heretofore not thought applicable, such as maintenance, plant transportation, storerooms, tool and die work, janitor service, and plant disposal of waste. Many of these activities, formerly

FIG. 14 SKIDS WITH REMOVABLE BOXES FOR WIDE-RANGE APPLICATION AND LONG-DISTANCE HANDLING BY USE OF ELECTRIC LIFT TRUCKS

considered indirect labor, are now considered direct labor and are written up as regular operations which are charged directly to the stock order. In the case of materials handling, the relation to productive labor is determined and the operation written up regularly. In costing, as has already been suggested, this item is regarded as direct labor and included in the cost of the product rather than in the overhead as an expense item.

Investment in handling equipment is an asset. Interest paid on unmoving stock is a liability. Decreased stock, under normal conditions, is the resultant of shorter manufacturing cycles, and the latter is a resultant of efficient handling methods, where 80 per cent manufacturing labor cost is the handling. There is no better way to cut costs than to simplify: (1) Designs, (2) tolerances, (3) tools, and (4) handling.

Discussion

W. W. BURDEN.[2] It would be interesting to have an analysis of the types and total footage of the various conveying systems in

[2] Anchor Steel and Eng. Co.

a plant like that of the Westinghouse at Pittsburgh and to know the trend as to type. Has there been found much opportunity in such a plant to substitute continuous movement of product and materials in place of intermittent movement, or are the operations so diversified that continuous movement in the main is not practicable? Likewise, it would be very interesting to learn the ratio of overhead handling to floor handling and the limitations of each.

MH-52-13

Conveyor Handling Methods of the Chicago Daily News

By MATTHEW W. POTTS,[1] NEW YORK, N. Y.

In this paper the author describes the conveyor handling system as installed in the plant of the Chicago Daily News. Continuous conveyors are used to handle rolls of paper from railroad cars and barges to the storage room, and then to the reel room. Conveyors are also used for handling stereotype plates to the press room, bundles of papers from the presses to the truck platforms, and mats from the makeup room to the stereotype room.

IN THE HANDLING of heavy loads and those of large dimensions it is the usual practice to use electric lift trucks, overhead monorail hoists, etc., and very seldom is it possible to install a continuous conveyor system for this class of commodity. The exception is the plant where the buildings or layout is designed around the handling system or with a definite handling system in mind.

The mechanical-handling installation at the Chicago Daily News uses continuous conveyors of unique design and application, and embodies a close cooperation between the design of the buildings and a definite layout of handling. Fig. 1 gives a general view of the complete conveyor installation for handling rolls of paper from railroad cars and barges to the roll storage room, then the reclaiming of these rolls and delivering to the reel room. It also shows a conveyor for handling stereotype plates to the press room and conveyors for handling bundles from the presses to the truck distributing platform, and a small installation for handling mats from the makeup room to the stereotype room.

It is seen from Fig. 1 that the railroad tracks are located in such a way that rolls can be taken from the railroad cars and put into storage without going through the first portion of the conveyor system. There is also a loading station on the ground floor with a turntable arrangement, so that rolls can be loaded to the elevator from trucks, or they can be unloaded from trucks direct to the reel room.

As much of the paper comes from mills located so that boat shipment can be made it was necessary to provide for quick unloading of these boats as they are not permitted to remain in the Chicago River over night. The boats carry approximately 1200 to 1500 rolls, and it is desirable to unload this in one day if possible so as to avoid the necessity of taking the boat out and bringing it back. This seems like a small matter, but the cost of the boat plus the lift-bridge charges, etc., make it a costly operation. When unloading from the boats the rolls are rolled onto the unloading dock and then are placed on the lowering skip. These rolls run in three sizes, the maximum being 40 in. in diameter, 6½ ft. long, and weigh 2200 lb. The skip is equipped with double carriers operating alternately, one ascending while the other descends, and this skip has capacity of 3 rolls per min. with a cable speed of 250 ft. per min. Fig. 2 shows the details of the skip and section *AA* gives a plan view of the unloading fingers for discharging to the apron conveyor in the tunnel. The conveyor and these fingers are shown in Fig. 3. On this operation the rolls are lowered approximately 46 ft.

After the rolls are discharged automatically to the apron con-

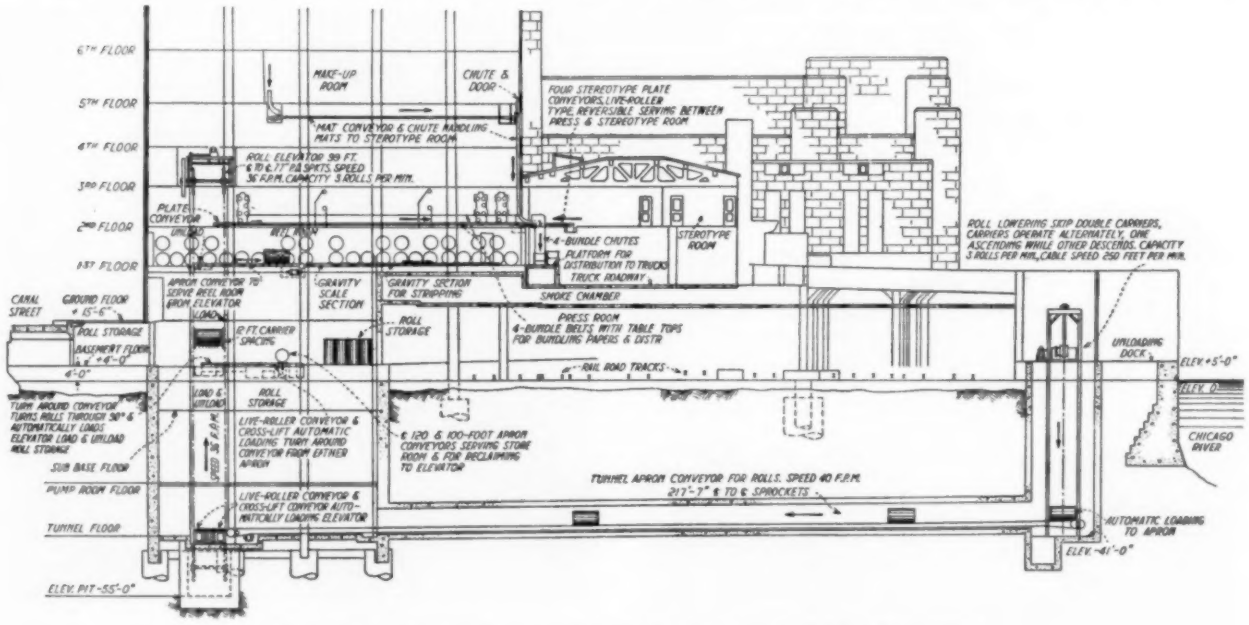

FIG. 1 SIDE ELEVATION SHOWING LOCATION OF CONVEYORS AND ELEVATORS

Presented at the Third National Meeting of the Materials Handling Division, Chicago, Ill., March 5 to 7, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

veyor they travel for approximately 220 ft. at a speed of 40 ft. per min. through a tunnel passing directly under the building. A view of the tunnel and the details of the conveyor are shown in Fig. 4.

It will be noted that the apron conveyor carries the rolls lengthwise, and when they discharge to the roll elevator they must be carried with the length across the carrier fingers so it is necessary to transfer from the tunnel apron to the loading fingers automatically, and at right angles. This is accomplished as shown in Fig. 5. This illustration shows the details of a definite automatic unloader and loading conveyor, and one which is unique in operation, being designed to meet a definite condition.

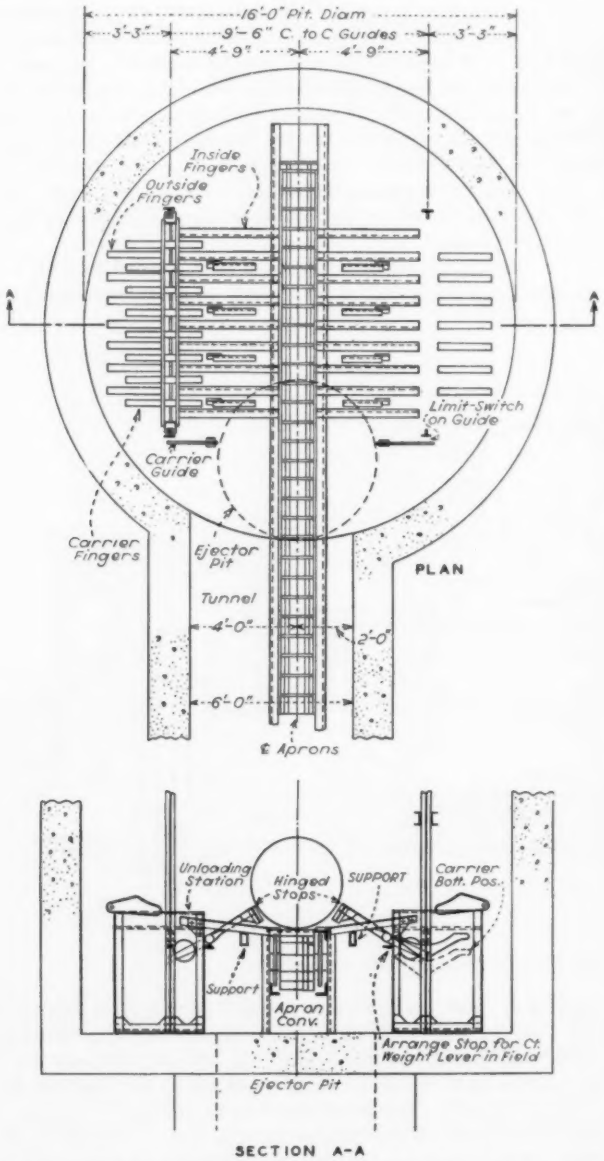

FIG. 2 DETAIL OF SKIP DISCHARGE SHOWING SAFETY FINGERS FOR STOPPING ROLL

As the roll leaves the tunnel apron it is fed onto a series of live rollers which are chain driven. The roll comes in contact with a

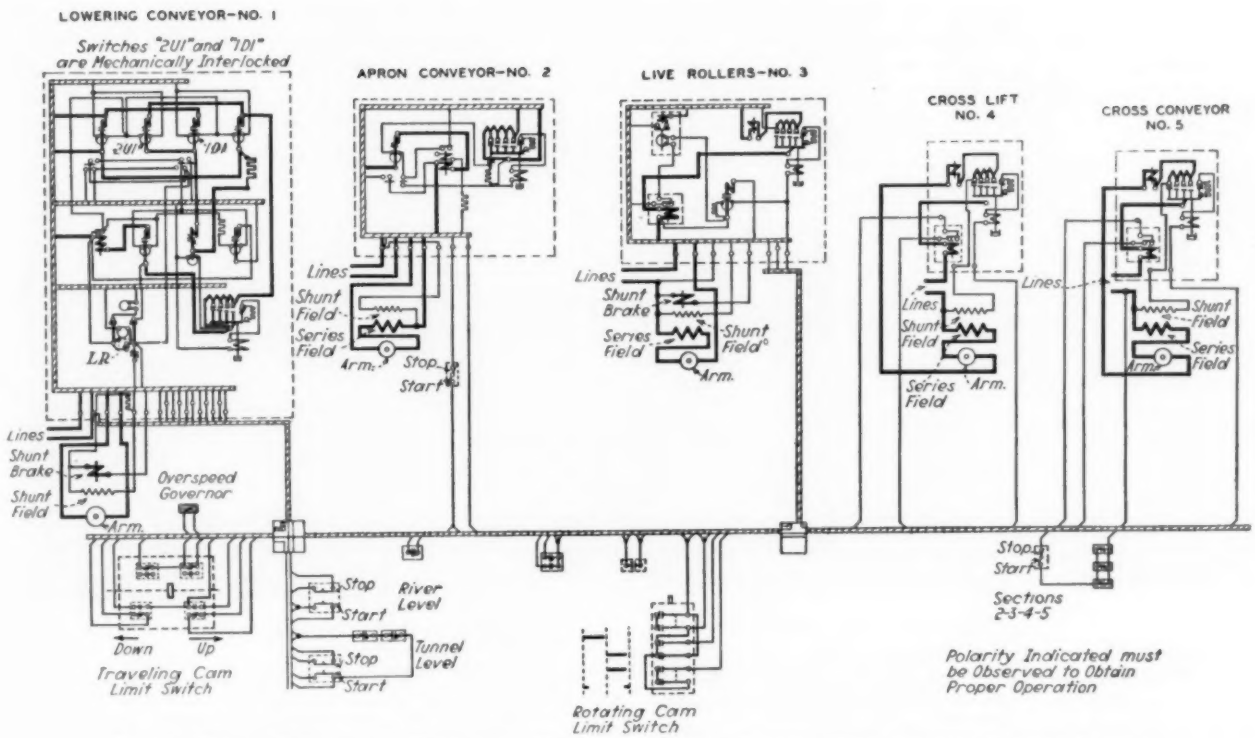

FIG. 6 WIRING DIAGRAM FOR CONTROL OF MOTORS ON TUNNEL CONVEYOR AND ADJACENT PART OF SYSTEM

bar which actuates the switch, stopping the live-roller conveyor and starting the motor on the lifting mechanism which raises the cross conveyor so as to take the roll of paper off the live rollers and at the same time propel it forward, discharging onto the loading fingers of the roll elevator. This seems in description

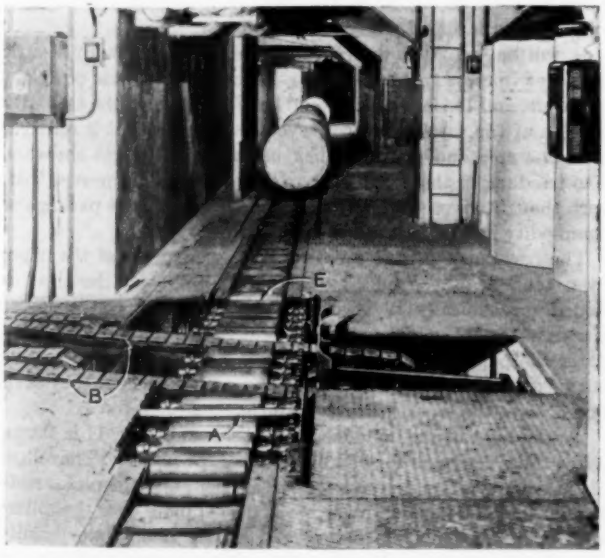

FIG. 7 TAKING ROLLS OUT OF STORAGE. NOTE HOW TRANSFER CONVEYOR IS DEPRESSED BELOW LIVE ROLLERS

to be a simple operation, but it reqiures considerable engineering to work out a device of this kind. Not only is it necessary to design the mechanical conveyors, but it is necessary to work out the exact location of the limit switches and the necessary cross bars, etc., for putting these switches in operation. Without going into details, the electric wiring diagram is shown with various circuits required for the lowering skip, the runnel apron, live-roll conveyor, cross conveyor, and cross-conveyor lifting mechanism. The roll elevator is approximately 100 ft. between center of sprockets and has a speed of 36 ft. per min. with a carrying capacity of 3 rolls per min.

As previously stated, on the rolls storage floor it is necessary to

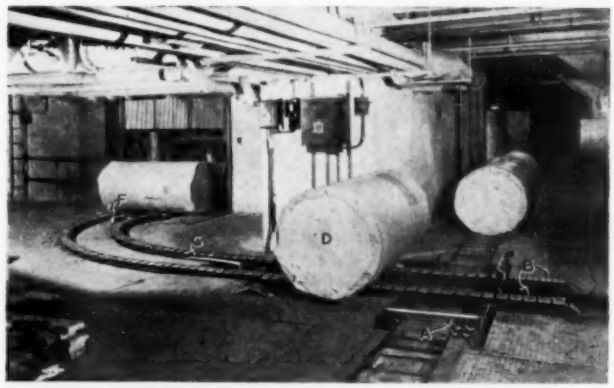

FIG. 8 NOTE TRANSFER CONVEYOR RAISED ABOVE LIVE ROLLERS AND METHOD OF TRANSFERRING TO CONVEYOR FOR GOING AROUND 90 DEGREE CURVE AND FEEDING TO VERTICAL ELEVATOR

take the rolls from the elevator and distribute them to the storage area, and also reclaim the rolls from storage, reload them on the elevator, and carry them to the reel room. A view of the special conveyors in this operation is shown in Figs. 7 and 9. In Fig. 7 are seen the rolls being reclaimed from storage, and they are being transported on an apron conveyor. The cross-lift conveyor is depressed and the live rollers at the transfer point are turning. The live rollers run continuously except when the cross lift is up. A closeup of the method of transferring from aprons to the

cross-lifting conveyor is shown in Fig. 7. When the roll comes in contact with cross-bar *A* the live-roller conveyor is stopped and the lifting mechanism of the two-strand chain conveyors marked *B* is automatically passed onto the two-strand chain conveyor which will carry the roll around a 90-deg. curve and discharge it to the loading fingers of the vertical elevator. The roller marked *E* is also attached to a switch which stops the apron conveyor in case the rolls are too close together or the cross-lift mechanism is raised. It will be noted that these conveyors are all protected with automatic electric stops as indicated by letters

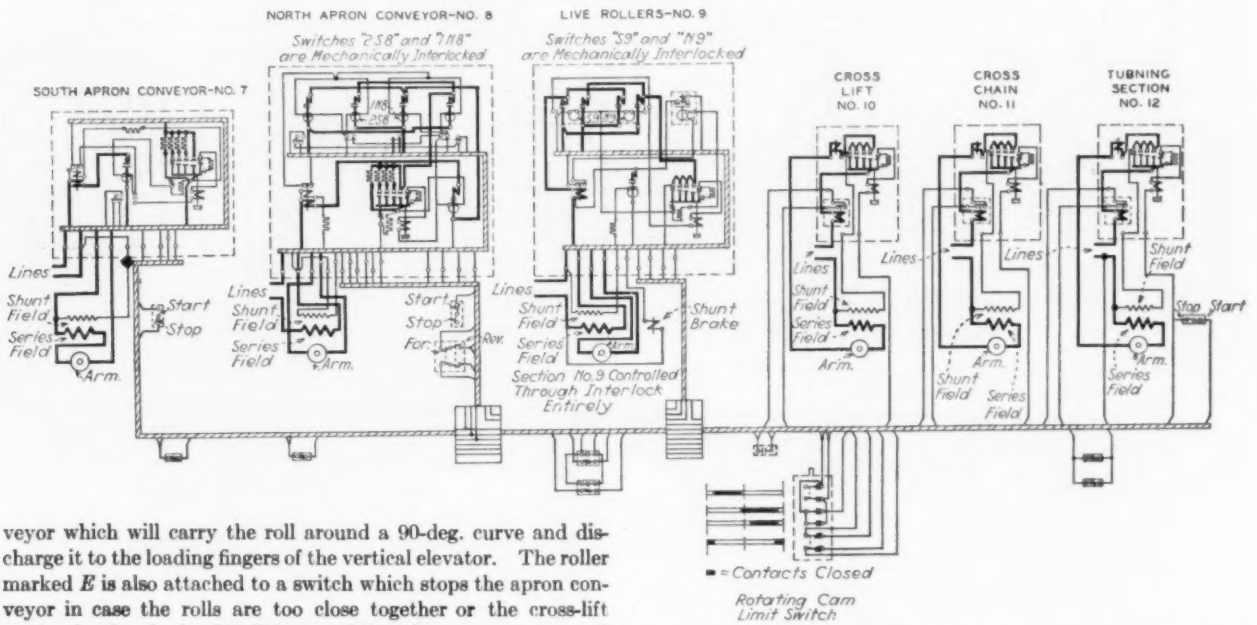

FIG. 9 ELECTRIC WIRING DIAGRAM FOR CONVEYORS ON STORAGE FLOOR AS SHOWN IN FIGS. 7 AND 8

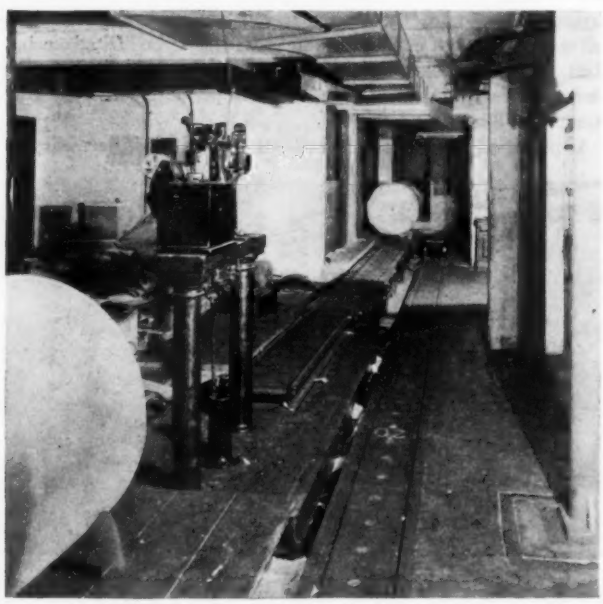

FIG. 10 NOTE ROLL BEING DISCHARGED FROM VERTICAL ELEVATOR TO DOLLEY CAR FOR STRIPPING

C and *F* in Fig. 8 and *A* and *E* in Fig. 7 so that their operation is entirely automatic. Again, without going in detail, in Fig. 9 is shown the wiring diagram for the conveyor shown in Figs. 7 and 8. These conveyors all have to be interlocked so as to prevent congestion, or jamming.

It is unusual to see chain conveyors operating round a 90-deg. curve, but the operation is entirely practical as is demonstrated in this installation. Of course, the conveyors have to be designed to fit the operation and sufficient radius must be allowed so as not to distort the chain. When discharging rolls from the elevator for storage on the basement floor the operation of the conveyors is reversed.

The unloading on the first floor or at the reel room is simple. As the apron conveyor passes in front of the elevator and with a simple discharge, the transfer is made direct to the apron or, if desired, skids can be placed over the apron and discharge can be made to a car as shown in Fig. 10. In this room the paper is weighed and stripped ready for the presses.

It will be seen that to try to handle these rolls with electric trucks or tractors and trailers would necessitate the use of freight elevators, and the labor cost would be higher than is the case with the use of the mechanical conveyors. The speed of 3 rolls per min. is ample and permits quick unloading of barges and cars. The handling of these unwieldy rolls of paper again proves that, with thought given to the problem, the most difficult package or commodity can be handled mechanically.

The newspaper presses are, in a sense, conveyors of the paper from the roll to the folded news sheet, but after the sheet is folded mechanically it is conveyed by special conveyors as shown in Fig. 11, which are specially designed for this operation. After the papers are bundled they are again discharged to belt conveyors which carry the bundles to a chute where they drop one floor to the truck-loading platform.

To the right of the bundle conveyor shown in Fig. 11 is shown a live-roller conveyor for handling stereotype plates. The rollers of this conveyor are driven by a friction belt, and the plates resting on the rollers move forward. The steel plate over the rollers acts as a guard for the plates, and at the same time permits operators to step over the conveyor without danger of slipping on the rolls. In this plant there is a battery of four of these conveyors for handling plates to the four lines of presses, and these four are practically the same as those shown in the bay illustrated in Fig. 11. There are also four belt conveyors for handling bundles of papers after they are tied, and the table over the top of the belt is used for some of the tying-up operations.

It is always interesting to know what horsepower is required

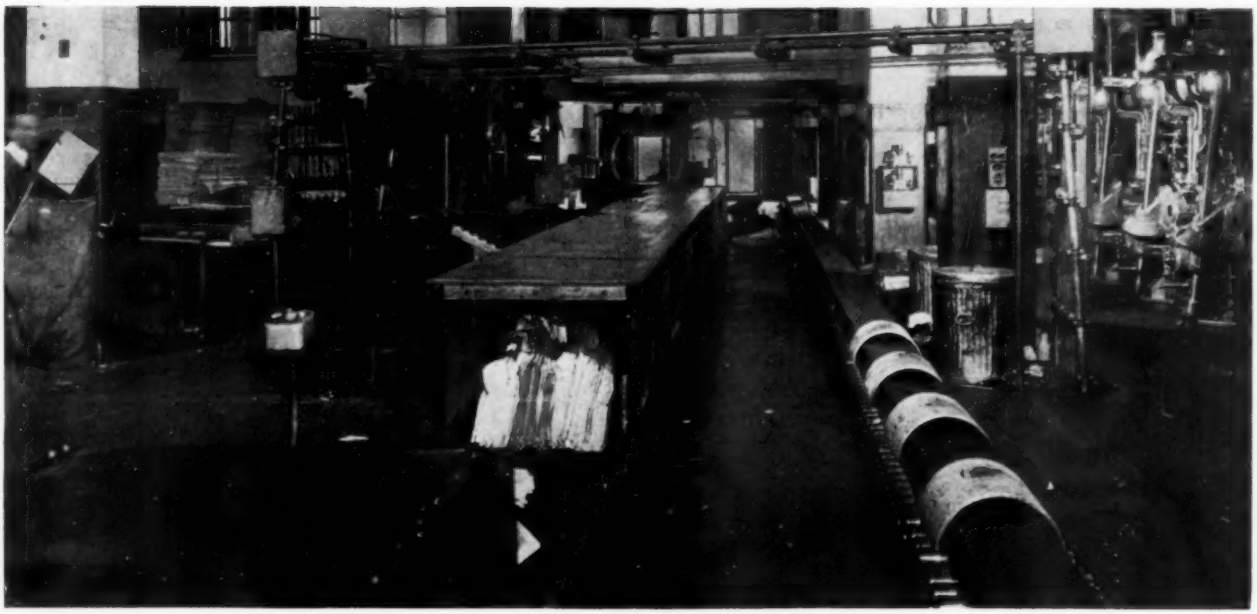

FIG. 11 PARTIAL VIEW OF PRESS ROOM SHOWING PLATE, PAPER, AND BUNDLE CONVEYORS

to operate mechanical-handling equipment. The power of the motors on the various conveyors is as follows: The roll lowering skip requires 15 hp. equipped with a 10-in. solenoid brake, traveling on a cam limit switch. The tunnel-apron conveyor requires a 15-hp. motor. The tunnel live-roller conveyor is equipped with a 3-hp. motor and 8-in. solenoid brake. The cross-conveyor lift for raising rolls off the live roller is equipped with a 5-hp. motor, a rotating cam limit switch, and an 8-in. solenoid brake. This is only for raising the conveyor, while the crossed conveyor itself is equipped with a 3-hp. motor for driving. On the basement or roll-storage floor, each of the two long apron conveyors require a 10-hp. motor. The live-roller conveyor is equipped with a 3-hp. motor and an 8-in. solenoid brake. The cross-lift conveyor is equipped with a 5-hp. motor, a rotating cam limit switch, and an 8-in. solenoid brake, while the drive for this conveyor is 3 hp. The turn-around conveyor is equipped with a 3-hp. motor. The main-roll elevator is equipped with a 40-hp. motor, a 14-in. shunt brake, and an overspeed governor. The motors required for the live-roller conveyor and the belt conveyor are small and, therefore, not listed. While these motors seem to be large, if consideration is given to the operation and the loads to be handled, it will be seen that they are not too large for the capacity required. This installation is a striking example of what can be done on a special handling operation.

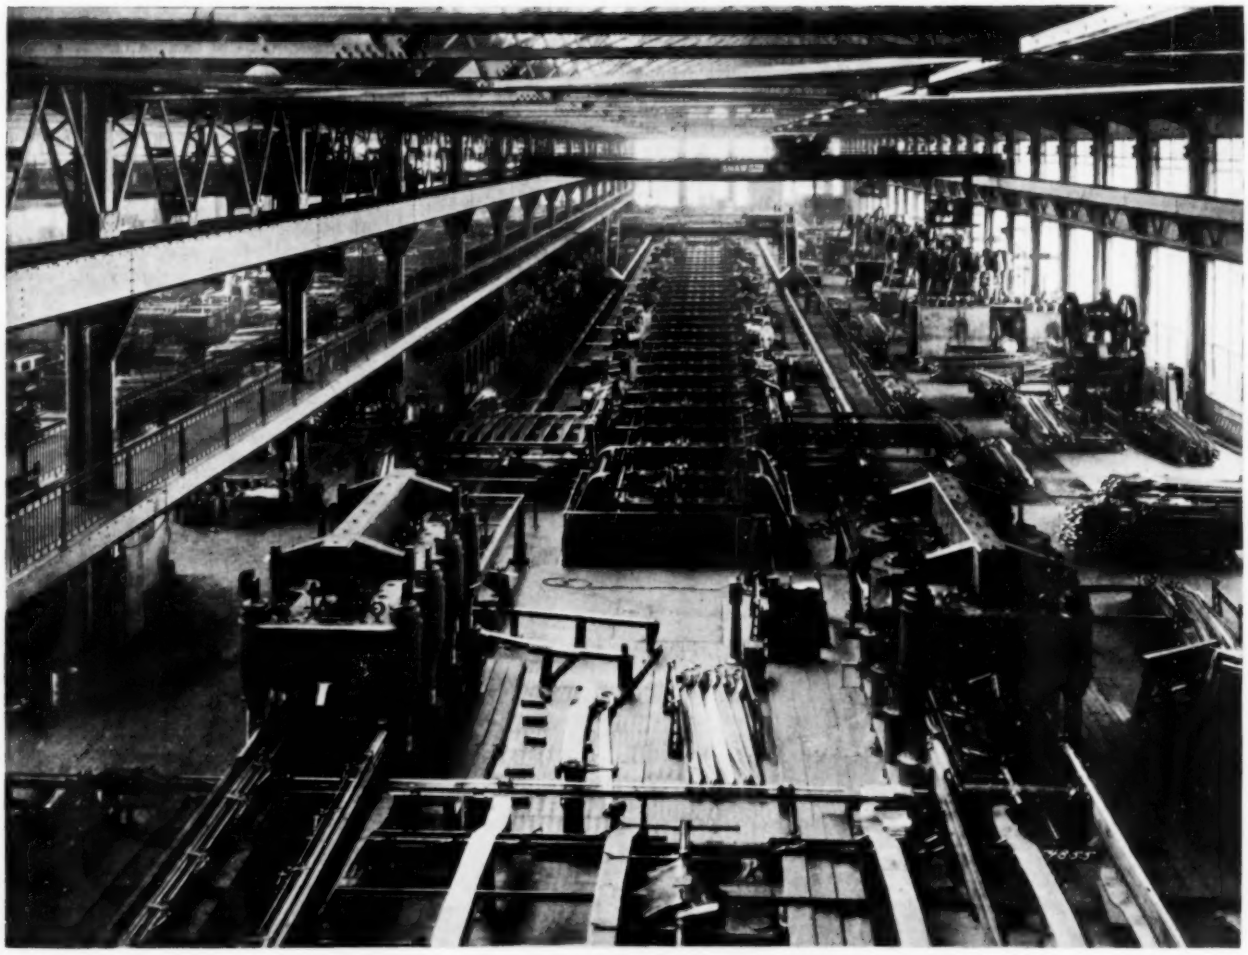

FIG. 1 SIDE-BAR PARTS ASSEMBLY LINE—FORMING PRESSES ARE IN THE FOREGROUND

Handling Materials in an Automatic Frame Plant

BY A. W. REDLIN,[1] MILWAUKEE, WIS.

ABOUT 25 years ago the A. O. Smith Corporation built the first pressed-steel automobile frame in America and has, ever since, remained a leader in this branch of the motor industry. This company also conceived and built the only automatic frame plant in the world, which was completed in 1920, after five years of intensive engineering and research development. The technical staff of the company designed, developed, and supervised the building and erection of the entire plant, and work on refinements and improvements is still being carried on. Today every operation from raw stock to the finished frame, including nearly all handling, is done with automatic machinery, and every part of this huge mechanical monster performs smoothly and with exactness 24 hr. a day for long periods without involuntary shut downs.

The automatic frame plant is divided into two main portions;

[1] Assistant Works Manager, A. O. Smith Corporation. Mem. A.S.M.E. Mr. Redlin served his apprenticeship with the Allis-Chalmers Company, following graduation from high school and a course in Mechanical Engineering. He rose through the ranks of his present position after extensive training in shop practice and factory management. Beginning in 1913 as toolroom foreman with the Brown Motor Company, Milwaukee, he held positions of increasing responsibility with various motor companies, until in 1923 he became connected with the A. O. Smith Corporation.

Presented at the Third National Materials Handling Meeting, Chicago, Ill., March 3, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the storage building in the rear, and the manufacturing building. In the former is storage space for 50,000 frames as well as 50,000 tons of raw material. Here the raw stock is also received, inspected, and pickled; furthermore, the assembled frames return here to be washed, painted, and dispatched either to storage or shipping platforms. The other main portion, the manufacturing building, houses the bulk of automatic machinery which changes strip steel into complete automobile frames. The actual work is done on the second floor, while the drive and auxiliary equipment extends down to the ground floor.

Steel flows through the plant in a $1^1/_2$-hr. journey, which changes the rusty piles of strip steel into shiny, enameled, precision articles at the rate of one every 8 sec. The strip steel, made to exacting specifications, is picked up from the cars with monorail cranes and is run through an inspection machine at the rate of 900 pieces per hour; being straightened, the length, width, thickness, and curvature of the strips checked, any piece found defective automatically thrown out, and satisfactory blanks delivered in piles to monorail cranes, which move them on to the pickling machine. Here the steel is placed in special crates of 5-ton capacity, which are handled through the different baths by means of a crane operated with remote control. Following pickling, the strip stacks are again picked up by monorail cranes and moved into the manufacturing building at the feed-ends of the two main lines.

Two major types of parts, side rails and cross members, go to make up a frame. Due to their different peculiarities and lengths they each have separate systems of machinery leading to the far end of the building where one large unit takes care of the general assembly of the frame.

The pickled steel passes through the side-bar press line with its four operations entirely handled by conveyors. First the straight strip is "kicked up" edgewise in order to follow the desired contour of the side rail. Next the numerous rivet holes and other openings are pierced, requiring separate presses for the right- and left-hand rails. This is followed by a single blanking press which trims the outline of the blanks, whereupon two more presses take care of the forming operation, folding up the flanges to obtain the conventional channel section. The feeding and unloading of each of these presses is done automatically, and all these many movements are timed and synchronized into a single unit, which does not require manual labor at any point.

Before the side rails can be assembled into a frame, a number of spring hangers, brackets, and other attachments must be riveted on, the ends must be clipped off for accuracy, and certain holes pierced, which must come very close. All this is done in the unit called the "Side-Bar Parts Assembly." Right- and left-hand bars are handled in pairs simultaneously, and are loaded onto trucks automatically. This machine is about 350 ft. long, has 38 trucks and 19 stations, at each of which adjustable machines are performing the various operations required. The finished side bars are automatically removed from the trucks at the end and inspected before being delivered to the adjacent general-assembly unit.

FIG. 2 SIDE-BAR PRESS LINE SHOWING FIRST FOUR PRESSES

Going back to the point where the strip steel enters the manufacturing building, the stacks, meant for cross members, are deposited by the monorail cranes at the loading ends of four cross-bar finishing lines. Each of these is equipped with blanking, piercing, and forming presses, very similar although smaller than corresponding machines for the side-bar press line. Like them, the cross-bar presses are fed automatically and all handling is done with automatic machinery, and following the press line is a conveyor which has a purpose similar to the side-bar parts assembly line. However, much less work has to be done on cross bars, requiring proportionally less space. At the end, the finished cross bars arrive at the general-assembly unit like the side bars.

The general assembly performs two important functions and does both entirely automatically. It collects all the required parts for the frame, assembles them, and puts in all the rivets, finally "setting" each rivet by forming the rivet heads. One conveyor system with trucks takes care of the first function, a so-called "Nailing Machine" assembles the frame and puts in the rivets, while another conveying system equipped with other trucks, handles the last function, the riveting. All three sub-units are synchronized and operated with one single motor.

When the frame is stripped off its truck at the discharging end it is finished and ready to leave the manufacturing building. On a conveyor, running the full length of the building it travels back to the storage building, while on the way it is carefully inspected, and if any part is wrong it is side-tracked on a special repair line and then sent on its way again.

Arriving in the storage building it first has to pass through a washing machine where grease, dirt, etc., is removed in a special automatic machine. Clean and dry it lands at the painting machine. Hanging, one close to the other on an endless chain, the frames slowly pass through this giant machine where special priming paint is sprayed on at the rate of 750 gal. per min. They pass through an oven, baking the paint, then through cooling chambers, emerging after 40 min. as a finished product ready for the customer.

Almost every conceivable type and design of conveyor is used in this automatic plant. Under the pressure of necessity, inventive skill has here brought out a startling variety of material-handling devices. Many old and approved means were utilized, but in addition a great many entirely new devices were invented.

The common reciprocating rail feeder found use in many instances as for the inspection machine and the side-bar and cross-bar press lines. However, it appeared in many new and clever applications. Almost invariably cams were employed for their drive, since intricate timing had to be followed. On most of these feeders it was sufficient to use gravity dogs, one set moving and another stationary. One high-speed conveyor, however, had to be equipped with positive disappearing dogs necessitating one added motion. Adjustable end-guards took

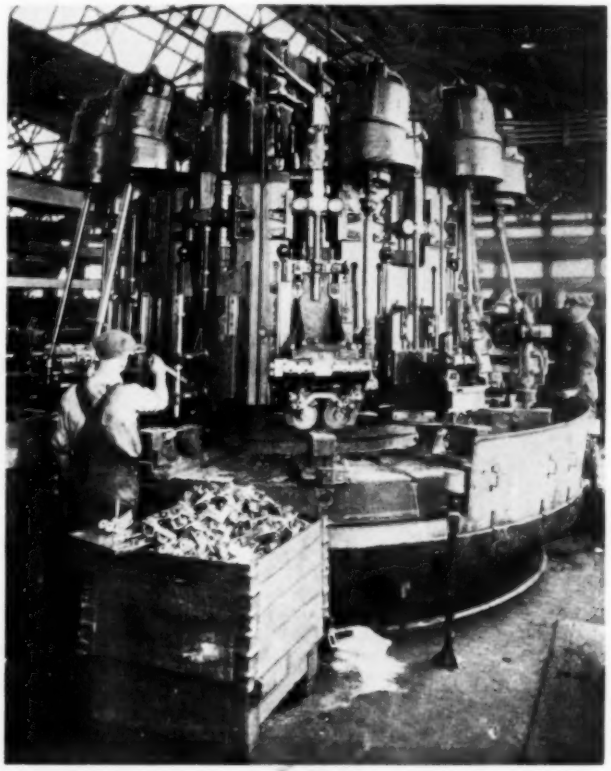

FIG. 3 AUTOMATIC SPRING-HANGER MACHINES—450 CASTINGS PER HOUR MACHINED COMPLETE AT ONE SETTING

FIG. 4 GENERAL ASSEMBLY UNIT WITH RIVET-NAILING MACHINES IN THE BACKGROUND

FIG. 5 OUTSIDE FRAME STORAGE—CAPACITY UPWARD OF 200,000 FRAMES

care of guiding the blanks and, as on nearly every type of feeder, safety devices were provided, which automatically stop the whole unit in case anything goes wrong.

A very interesting solution of a feeder problem is a double reciprocating overhead carriage operated with wire ropes for the feeding and unloading of the off-setting press. This device picks up the steel strip with magnets and does a perfect job at very high rates of speed.

Another clever device feeds and unloads the forming presses. It has disappearing fingers which simultaneously pick up a blank from the cross conveyor underneath and a finished side bar in the press; then rushes 20 ft., stops, and deposits the bar in a crate and the blank in its exact position on the forming die. Split seconds and perfect timing are absolutely essential here and it is well safeguarded by sensitive electrical devices.

Feeders and such devices are, however, to be found in many plants and in connection with many machines, but entirely new problems faced the designers of the side-bar parts assembly line. Thirty-eight trucks, each one a real machine in itself, with four smaller carriages, had to be put through their paces according to a very difficult timing diagram. Swift movements, sudden and accurate stopping and starting of such great masses involved staggering loads and an inertia which could not be overlooked. Enormous cams, of a size and design nowhere else to be seen operate this machine, and powerful balancing devices are provided to absorb the suddenly released energy. Running on rails, the trucks advance intermittently on an upper level. At each station the trucks are doweled, the smaller carriages are simultaneously released, thrust out two to each side and also doweled, thus carrying the side rails, to be worked on, into the waiting machines. These quickly perform their work; the carriages retreat and the trucks advance to the next station where the same cycle is again repeated; each consuming a total of but 8 sec. At the end of the line, truck after truck is unloaded and lowered onto the return tracks on the lower level, where a screw-like device propels them back to the starting end at uniform speed. Raised to the upper level by means of an elevator they receive new loads and repeat the performance.

In magnitude and completeness it has nothing on the next unit, however, which is the general assembly. Here two track systems with trucks are combined into one unit, weights are still greater, and the assembling and nailing machine adds to make this one of the most complicated and, to the visitor, most baffling machines to be found any place. The powerful drive, with its string of enormous cams, resembles that of the preceding unit, the side-bar parts assembly line. In one respect, however, does this unit present a new angle of conveying. Unlike the previous unit, the work is not brought up to the machine, but the frames, now assembled, stay on the trucks while the machines are brought to the work. This is accomplished by having the

riveting machines mounted on platforms, provided on each side of each truck line. A stationary steel floor over the platforms makes it possible for the men to walk around among the individual machines. The procedure is then for the trucks to run intermittently, stopping for a given length of time at each station. Here the truck with the frame on it is lifted up on dowels, the riveting machines advance from each side, carried on the platforms, and perform their work of setting the rivet heads. Very ingenious heads were invented which enable any rivet to be set no matter how it is located, with a few standard types of machines. After the work is done the jaws of the machines open up, the machines retreat, and the trucks then advance another step and the whole performance is repeated.

The average frame is composed of some 125 parts and 500 to 600 operations are required to produce the finished frame. The automatic plant alone turns out 10,000 such frames every 24 hr., the machinery performing approximately four million operations in a day's production. It is indeed a sizeable figure, and it means something when one considers that every one of the operations must be performed correctly, or such a plant would not be practical. Still more significant is the feat of manufacturing the more than 100 parts for a frame in as many different places in the plant, to have them meet at one place on schedule, to piece them together at the rate of a complete unit every 8 sec., and to repeat this accurately 10,000 times in succession every day. Visualize what it means to produce springy, flexible-steel stampings so accurate and so uniform that any one piece will match any accompanying frame part so perfectly that no interference ever occurs, and so that all holes line up exactly. This is not only desirable but absolutely necessary since only a fraction of a second is available to put in all the rivets.

It may be of interest to mention that more than 100 tons of steel flow through the automatic plant every hour and a half. Transportation facilities, accordingly, must have an unusual capacity. The tremendous production of 10,000 frames per day also calls for rapid disposal. Storage space is available in the building and outside the building, which will accommodate 150,000 frames. Extensive loading platforms are also provided from which as many as 12,000 frames have been loaded into cars in 9 hr.

It takes 50 min. actually to manufacture a frame in the automatic plant. An added 40 min. is consumed in cleaning and painting the frame before it is ready to be shipped. This makes a total of $1^1/_2$ hr. for the entire fabrication process.

The manufacturing building has a productive capacity of 450 assembled frames per hour, and in order to supply parts, each unit preceding the general assembly has a capacity of 450 pieces per hour. For similar reasons it is necessary to have the same capacity for the raw-material handling machines. Thus the inspection machines can handle 900 strips per hour, the pickling machines upward to 1100 tons of steel per day, and finally the painting machine can turn out 450 frames per hour.

Fully automatic production is already common practice in bulk manufacturing. What this company has accomplished shows that the principle can be applied successfully and on a large scale to assembly operations. If experience is any guide, a more complete use of machinery for all routine operations and the handling of materials is not only possible but also very profitable.

Progress in Machine-Shop Practice

Contributed by the Machine Shop Practice Division

Executive Committee: W. J. Peets, *Chairman*, Carlos de Zafra, *Secretary*, K. H. Condit, W. W. Tangeman, and J. W. Roe

MEASURED by the advances in machine-tool design, the progress in machine-shop practice during 1929 has been considerable. Since the greatest part of any possible advance in this art centers about the availability of improved production equipment, this particular measure is probably as significant as any that could be selected.

The second machine-tool exposition held by the National Machine Tool Builders' Association served to introduce a record number of new pieces of machine-shop equipment. This show took place in Cleveland early in the autumn, and was attended by some 25,000 visitors, almost all of whom were the chief executives, operating heads or specifying officials of machine-tool using organizations. Many men of long experience in the industry expressed the conviction that never before had so many prominent men of the industry gathered in one place. And they were well repaid for coming, because they saw in operation something like 150 new machine tools, as well as many others that had been on the market for some little time, but were still sufficiently recent in design to be far in advance of much of the equipment that is now in use.

The following statement, taken from the Show Number of *American Machinist*, outlines the more important developments:

"The substitution of automatic for hand operation on a number of the machines developed is a prominent feature in the equipment placed on exhibition. Wherever feasible this improvement has been made. Such developments have demanded no little skill and ingenuity on the part of the machine designer and builder. Radical changes were required in most cases. The resulting equipment requires more care in set-up, more certain means of lubrication, and may involve a higher maintenance charge on account of the refinement of parts introduced. On the other hand, sturdiness has been added in most cases in developing or redesigning such types of equipment. Adjustments in its use, of course, must be made by skilled mechanics who are experienced in special machines, rather than by the ordinary machine operator. But to offset any increased initial cost, and any added operating or maintenance expense, a vast increase in output has been brought about, making the unit cost of products manufactured only a fraction of what it was when former types of equipment were employed.

"Mechanical features of operation are well typified by a feeding device developed and applied to one of the well-known lines of automatics. No operator is now required for this machine. A long runway holds a store of the work, and the two-arm work-feeding mechanism picks up one part at a time and brings it into position between two tool-holding slides, one of which carries turning tools, and the other grooving, facing, and forming tools, where it is held between centers. The work is driven by the mechanism. When the machining has been completed a second arm automatically moves up and discharges the piece on a runway carrying it away from the machine, while the first arm moves in a new part for machining. The machine continues to operate in this way until stopped by the push-button control.

"The present tendency in machine design is rather away from the single-purpose machine. For high production and very special work the single-purpose tool, of course, will always find a market. But its limitations when sudden and radical changes in the design of products come about are causing machine-tool builders to devote much less attention to this type of equipment, and more attention to the provision of special fixtures adapting standard tools to definite production jobs, and to the design of unit-type equipment to be built up into various combinations suited to the requirements of different jobs. This tendency is most decided and undoubtedly will continue to be a major factor in machine design for a long time to come.

"Even in cases where machines have been developed for special purposes there have been introduced certain features which widen the uses of the equipment. For instance, a certain type of grinder designed for special railroad equipment work on a production basis has been adapted so that the machine can be used for tool grinding or production grinding on other types of work.

"There is a definite tendency toward a more extensive use of hydraulic mechanisms on numerous types of machine tools. At the show, new applications of hydraulic feed to equipment such as lathes, grinders, smaller sizes of milling machines, multiple-spindle drills, honing machines, and broaching machines were demonstrated. Further improvements in indexing have been made on machine tools placed on exhibition this year. One outstanding development is the application of the double Geneva motion on a work-rotating chucking machine with an unusually large turret that is indexed in four positions 90 deg. apart. This machine also represents several other outstanding developments in machine design.

"Increasing attention to lubrication is decidedly evidenced by the equipment developed during the past year. No definite tendency toward any one type of lubrication is to be discovered. Some manufacturers have adopted central, forced-feed systems for their equipment. Others prefer gravity feed from central reservoirs. Still others retain the oil cups for individual bearings. Combinations of systems are also of frequent occurrence. For instance, the chucking machine mentioned employs a central lubricating system for the main bearings of the machine, but a gravity-feed reservoir for the heavy turret, to avoid the use of slip joints which would be required if the main system were utilized for turret lubrication. One manufacturer is introducing a forced-feed lubricating system operated periodically under the control of an electric timing clock. Oil filters are also finding more extensive application. In no case is lubrication neglected as a factor in machine operation and maintenance.

"Many other factors have become of increasing importance in machine design during the past year, and characterize practically all of the equipment placed on exhibition at the show. Among those factors which have received special consideration are: A higher degree of accuracy in the parts comprising machine tools and equipment, provisions for a higher degree of accuracy in the products turned out, ease and convenience of operation, reliability of service, compactness of design, decrease of floor space occupied, simplicity of drive, reduction of power consumption through the liberal use of ball and roller bearings, higher grades of steel and alloys for journals, spindles, gears, and other operating parts of machines, convenience of inspection and cleaning, provisions for the removal of chips, facilities for mechanical handling, and the features of higher production, greater automaticity, and adequate lubrication, which have been discussed."

Further evidence of the ability of machine-tool builders to cooperate was given by the adoption of a standard color for machine tools. With very few exceptions all machines exhibited at Cleveland were finished in this color, and the pleasing appearance of uniformity was sufficient justification for the move. Most of the builders who have adopted the standard color are making a small extra charge for finishing their products in a special color specified by the customer.

Because of the high rate at which machine-tool plants have been operating for the past year, the designing and building of the new models exhibited was attended by considerable difficulty. In fact, some of the innovations intended for Cleveland were not finished in time and will be announced later. This situation augurs well for the future. Not only are there more new machines on the way, but because of the record-breaking activity of the builders, profits have been more nearly commensurate with the efforts of the engineers and construction forces, and consequently there will be more money in the future for the research work that must be done if the art is to continue to advance.

The facilities of the machine-tool building plants have also been increased during the year. Several new engineering buildings have been erected, and plant additions have been made to take care of greatly increased orders. Overtime and double shifts have been common throughout the industry.

Undoubtedly the most important single development of the year has been the progress made in adapting the new tungsten carbide cutting tools to machine-tool uses. It must be admitted that many disappointments have accompanied the efforts to apply tungsten carbide, but these were to be expected, and on the whole there has been appreciable progress.

Unqualified success has attended the application of this material to the machining of rubber, fiber, and similar materials; and to the machining of brass, bronze, aluminum, and the like; also in most cases where cast iron has been the material to be cut. But like success cannot be reported in cutting alloy steels. Here the fragility of tungsten carbide incident to its extreme hardness has led to failure where there was the least chance of chatter. Much of the difficulty is now attributed to the means of holding the cutting bit to the shank of the tool. Brazing, atomic-hydrogen welding, and more recently mechanical means such as dovetailing have been used for this purpose, but with results that indicate the necessity of further research.

It must be admitted that there has been considerable disappointment at the failure of this new cutting material to solve all the difficult machining problems of the shop, but it should be observed that much of this disappointment is entirely unjustified, and should not lead potential users to distrust its future possibilities. Too much was expected of a substance about which there was insufficient knowledge. When that knowledge has been obtained there is every reason to believe that tungsten carbide will do all that has been claimed for it.

A year ago there was a general belief that tungsten carbide would bring about an immediate revolution in machine-tool design. This belief has not been realized. A few machines have been speeded up to meet the requirements of the new material, but at least some of the more recent designs have been found quite adequate to develop the full possibilities of it. Evidently the change in design is to be an evolution rather than a revolution.

An interesting effect of the introduction of tungsten carbide has been the improvement in high-speed steels. The threat of competition has driven the producers to extra efforts, and the result has been that some of the current products show cutting ability as much as 25 per cent ahead of anything that has been available hitherto. Further advances are probable, especially because experience with tungsten carbide will accustom the user to the brittleness of a diamond-hard alloy, and will thus lead him to accept some lessening of the toughness of high-speed steel if it can be made harder. When the user accepts this situation the maker of high-speed steel can develop steels with entirely new characteristics.

While the new cutting materials have occupied the center of the stage, developments of other new materials used in the machine shop have proceeded apace. Among the important ones is high-test cast iron, practically a new material. Cast iron of as high as 85,000 lb. per sq. in. tensile strength has been produced, and one foundry is consistently attaining strengths of 65,000 lb. Four processes are in use, all depending on the holding of the liquid iron at a high temperature, in the neighborhood of 3000 deg. fahr., until the carbon has been dissolved, thus preventing the formation of the plates that weaken the structure of ordinary iron.

The research organizations of the aluminum, brass, and nickel companies have perfected many new alloys and improved older ones. Plastics have come very much into favor, and are replacing metals in some instances. "Stainless" steels have attracted considerable attention, and nitrided steels have found new uses.

All of these advances point to the need for more and better organized research work in the machine-shop-practice field. A little is being done by a few of the larger units, but in the aggregate not much has been accomplished. From the very nature of machine-shop work, and the absence of any shops of dominating size, the problem of how to organize research of the kind needed is difficult. Probably the only solution is a central institute or laboratory to be supported by contributions from the various trade associations and individuals in the industry, but before such an institution can be established there must be an awakening to the true significance of fundamental and applied research. Much educational work lies ahead of any group undertaking to solve this particular problem, but the necessity is so great that it will justify large effort.

Standardization work in the machine-shop-practice field is in somewhat better shape than is research. Only one standard has been approved by the American Standards Association during 1929, that for tool-holder shanks and tool-post openings, but the following are in type and are practically completed by the sectional committees: Spur-gear tooth form, full depth system; inspection of gears; gear materials and blanks; taps, cut and ground threads; milling cutters; radial ball bearings; slotted-head screws; line work on drawings; and motor-frame dimensions.

During 1929 some progress has been made in improving management methods, and particularly cost methods. The outstanding example is the work of the National Machine Tool Builders' Association under the direction of its general manager and his staff cost consultant. Much progress has been made in getting uniformity of cost methods so that true comparisons are really possible. By this means the plant management can tell with some assurance whether it is efficient as compared with its competitors. Other branches of the field would do well to take steps toward the same goal.

Management throughout the industry has evidently accepted the soundness of the modernization principle. The greater part of the record business of 1929 has come from replacements of obsolete equipment rather than from plant enlargements. A certain amount of replacement business has had to be postponed by equipment builders because of their inability to make deliveries. The recession in the automobile industry, and the general slowing down that seems likely until the confidence shaken by the recent stock-market gyrations has been restored, will give an opportunity for the builders to catch up on their orders, and put their full effort into campaigns to replace the vast quantity of obsolete equipment still in use.

Power Required to Drill Cast Iron and Steel

By O. W. BOSTON,[1] ANN ARBOR, MICH., AND C. J. OXFORD,[2] DETROIT, MICH.

This paper presents the results of drilling tests on cast iron and steel. Drills ranging in diameter from 1/2 to 1-1/2 in. of the standard twist-drill type were used. The drills were considered sharp in all tests. A coolant consisting of one part of soluble oil and 16 parts of water was used in all tests. The materials cut consisted of one regular machining cast iron and one cast iron made up of 20 per cent charcoal pig iron, together with 17 steels of a wide variety of chemical analyses, which were selected to cover the steels commonly used in modern manufacture.

Data as to drilling torque, thrust, computed horsepower at the drill point, and net horsepower supplied to the machine as measured on a recording wattmeter are given under two headings: commercial tests and special tests. All commercial tests were run at a peripheral speed of the drill of approximately 60 ft. per min. The feed for each drill size was as near to those given in the usual commercial-drilling table as the change gears available would permit. They were as follows: 0.009 in. per rev. feed for the 1/2-in. diameter drill, 0.011 in. for the 5/8-in. drill, 0.012 in. for the 3/4-in. drill, 0.013 in. for the 1-in. drill and 0.015 in. for the 1-1/4- and 1-1/2-in. diameter drills.

Special tests were run on various cast irons and steels so that the influence of the speed, feed, and drill diameter could be determined, in order that the results of the commercial-drilling tests could be extended to cover any other conditions of drilling for each material. It was found from these special tests that the thrust for both cast iron and steel increased in direct proportion to the drill diameter d; that the torque increased in proportion to d^2 for cast iron and $d^{1.8}$ for steel. The thrust increased with an increase in feed f, but at a rate as slow as $f^{0.6}$ for both cast iron and steel. The torque increased as $f^{0.6}$ for cast iron, but $f^{0.78}$ for steel. It was found that the torque and thrust remained practically constant over the whole range of speeds covered from 74 to 441 r.p.m. for each drill size and feed.

An attempt is made to correlate the hardness values of the materials determined by the Brinell, Rockwell, scleroscope, and Herbert pendulum hardness testers, with the results obtained from the drilling tests.

It is concluded that no satisfactory relation exists between these properties.

THIS paper presents results of a series of tests in drilling steel and cast iron with sharp standard twist drills ranging in diameter from $^1/_2$ in. to $1^1/_2$ in. Data were obtained of the torque, thrust, and net horsepower developed at the point of the drill for some of the modern high-speed-steel twist drills, when cutting a variety of types of steels and cast irons used widely in modern industry.

Materials Drilled

The materials drilled in these experiments consisted of 17 steels and 2 cast irons. The steels were obtained in bars 2 in. wide by 4 in. deep and from 14 to 20 in. long. They were selected to represent a number of the more commonly used steels in industry. All materials are listed in Table 1. The steel bars are numbered from 1 to 16 inclusive, and 19, while bars 18 and 20 are cast-iron test pieces, also 2 in. wide by 4 in. deep and 4 ft. long, as cast in the University foundry. The bar number for each steel is given, with the S.A.E. specification, which, in some instances, is augmented by the chemical analysis.

The steels were given a heat-treatment at the mill, to provide a grain structure and degree of hardness which was thought suitable for machining purposes. These heat-treatments are indicated in Table 1. Cast-iron bar 20 was a regular high-silicon iron of the type commonly used for machining purposes. It consisted of C, 3.52; Si, 2.18; S, 0.108; Mn, 0.69; P, 0.489. Cast-iron bar 18, was made up of about 25 per cent by weight of charcoal pig iron.

[1] Professor, College of Engineering, University of Michigan. Mem. A.S.M.E.

[2] Chief Engineer, National Twist Drill and Tool Company. Assoc. Mem. A.S.M.E.

Contributed by the Special Research Committee on Cutting of Metals and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The surface, 1/4 in. in depth, was milled off the edge of each bar at the end so as to present a surface about 2 in. square. These surfaces were then filed smooth, after which hardness tests were made on them. The Brinell, Rockwell "B" scale, and scleroscope hardness numbers are also given in Table 1 for each bar.

Drills Used

The drills used in these experiments were furnished by the National Twist Drill and Tool Company, and were selected as being representative of those drills corresponding with their standard specifications for taper-shank, high-speed-steel twist drills. They were furnished in sizes of 1/2 in., 5/8 in., 3/4 in., 1 in., 1 1/4 in., and 1 1/2 in. diameter. Each size was furnished in duplicate, one stamped R and the other stamped L, for purposes of identification. The drills were ground in an S.P.K.

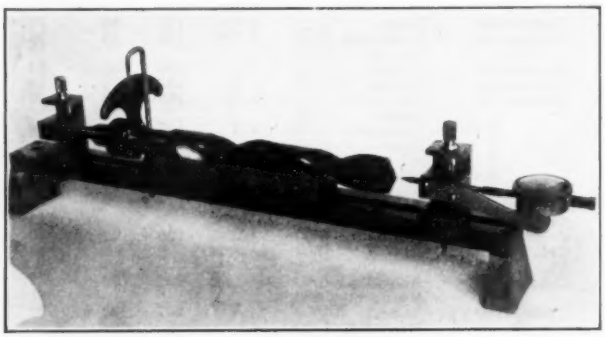

Fig. 1 Drill Measuring Instrument for Determining Cutting-Edge Clearance, and Advance

Blau drill grinder with a drill overhang from the jaws, varying for each drill diameter, as set by a gage, as follows:

Drill diameter inches	Drill overhang, inches
1/2	0.275
5/8	0.300
3/4	0.325
1	0.375
1 1/4	0.425
1 1/2	0.475

The head of the machine was also carefully set to the proper drill diameter, so that with the overhang specified, that drill could be reground without changing the various drill-point angles.

The grinder forms the drill point so that it has a conical surface back of the cutting edge. In each case after grinding, the drill was measured on the special measuring instrument shown in Fig. 1, which employed a dial gage with its spindle placed parallel to the axis of the drill, but off center to make sure that the cutting edges at the periphery were advanced to the same relative position or lead to cut chips of equal thickness.

1 1/4 L	1.2490	0.1595–0.1675	120	30	139		31		27	
1 1/2 R	1.500	0.1845–0.2135	121		138		31	20	29	
1 1/2 L	1.500	0.1873–0.214	121		135		31	30	29	15

Newly sharpened drills were again reground if one lip was in advance of the other by more than 0.001 in. This precaution was taken to eliminate any influence on the test results of any chip thickness other than that desired. If, for instance, a drill one inch in diameter had a variation in lead of one cutting edge over the other of 0.005 in., which is not uncommon in drill grinding, and the drill was being fed into material at the rate of 0.013 in. per revolution, the advanced cutting edge would remove 0.0115 in. feed per revolution, while the lagging cutting edge would remove only 0.0015 in. Inasmuch as thick chips are removed more efficiently, that is, with less power per cubic inch of metal removed per minute, than thin chips, the resultant torque and thrust, in the case of uneven chip thickness, might not equal those for a correctly ground drill.

TABLE 3 DRILL CLEARANCE ANGLES REQUIRED BY FEED AND AS ACTUALLY GROUND

Size of drill, in.	Letter	Outside diameter in.	Width of chisel point, in.	Practical feed in. per rev.	Feed helix At periphery Min.	Feed helix At chisel edge Deg.	Feed helix At chisel edge Min.	Clearance at periphery, as ground Deg.	Clearance at periphery, as ground Min.
1/2	R	0.499	0.115	0.009	20	1	25	5	20
5/8	R	0.625	0.15	0.011	19	1	21	5	0
3/4	R	0.7495	0.16	0.012	17	1	19	4	40
1	R	0.999	0.205	0.013	14	1	10	5	0
1 1/4	R	1.250	0.235	0.015	13	1	9	5	0
1 1/2	R	1.500	0.25	0.015	10	1	5	5	0

Table 2 lists the drills used in the tests, and gives the values of various measurements, such as the outside diameter, the web thickness at the point after the first grind and again after being ground at the conclusion of the tests, the point angle included between the two cutting edges, the chisel-edge angle or the angle the chisel edge makes with a cutting edge, and the helix angle of land measured at the point and at the shank.

The clearance angle actually ground back of the cutting edge at the periphery is shown for each drill in Table 3. These angles are approximately five degrees for all drill sizes. The clearance angles were determined graphically, with the use of a universal drafting machine, after rolling the twist drill over the back of a sheet of carbon paper placed on plain paper, and taking measurements from the print on the plain paper.

This actual clearance angle was also determined more accurately by the special clearance measuring instrument for one point back of the cutting edge, adjacent to the chisel edge, and a second point back of the cutting edge, adjacent to the periphery of the drill. The dial-indicator reading was set at zero for each position, when the point of the indicator rested directly on the cutting edge. The drill was then rotated 3 deg., and the new dial-gage reading observed. The dial-gage readings adjacent to the periphery and chisel edge were carefully determined for the 5/8-in. and 1-inch drills for each increment of 3 deg. for a total rotation of the drill of 60 deg. The gage readings were plotted against the angle of rotation in degrees, and lines were obtained which were practically straight. This proved that the clearance angle was constant at all points back of the cutting edge, for each position. Also, the two lines for each drill passed through the origin and practically coincided, showing that the longitudinal relief for a given rotation was the same at the periphery as adjacent to the chisel edge. These readings were then reduced to the clearance angle back of the cutting edge for the two positions, and values were obtained as shown in Table 4. It is seen that the clearance at the end of the chisel edge is more than twice that near the periphery for each drill size. The values of the clearance at the periphery as ground, shown in Table 3, differ slightly from those determined by the measuring instrument given in Table 4, for a point near the

outside periphery, first, because the angles were not measured at the same distance from the drill center, and second, because the values at the periphery in Table 3 were obtained graphically, using carbon paper, while those in Table 4 were determined analytically from the gage measurements near the periphery. The latter are believed to be more accurate. These clearance angles, while smaller than those usually specified, seemed adequate for the feeds used in this series of experiments, as in no instance was rubbing observed on the end of the drill back of the cutting edge.

The angles, or relief, back of the cutting edge on the end of the drill, as required by the advance of the drill or the feed per revolution (feed helix), at both the periphery and adjacent to the chisel edge, are given for each drill size in Table 3, for the feed in inches per revolution for each drill size, as actually used in the commercial tests. (See Table 5.) For the 5/8-in. diameter drill, operating with a feed of 0.011 in. per revolution, the feed helix at the periphery is zero deg. and 19 min.; at the end of the chisel edge it is 1 deg. and 21 min. The actual clearance between the end of the drill and the material, is the clearance angle as ground, reduced by the feed-helix angle required by the advance of the drill. The feed-helix angle at the periphery of the 5/8-in. R drill is zero deg. and 19 min., as shown in Table 3. The total clearance as ground is 4 deg. and 51 min., as shown in Table 4, so that the drilling clearance is the difference, or 4 deg. and 32 min. Similarly, the actual clearance at the end of the chisel edge for the 5/8-in. drill is 12 deg. and 22 min. (Table 4), less the feed-helix angle of 1 deg. and 21 min. (Table 3), or 11 deg. and 1 min.

Influence of Clearance Angle Variations on Torque and Thrust

In a series of experiments with a group of drills having point angles of 118 deg., but various helix angles, B. W. Benedict[3] showed that with each drill ground successively to have clearance angles at the periphery of 2, 4 1/2, 7, 10, 12 1/2, and 15 deg., the torque is practically constant. The drill diameter was one inch and the drill with each clearance was tested in cast iron at four different feeds, 0.0056, 0.0133, 0.0256, and 0.041 in. per revolution.

Considering the thrust, uniform and pronounced tendencies were observed. The thrust was highest for the lowest clearances and gradually decreased as the clearances increased to about 10 deg. when the curve which was concave upward, became practically horizontal.

Testing Equipment

The testing equipment was devised so that the torque and thrust as developed at the drill point could be determined, as well as the input or power developed by the motor. The testing equipment consisting of a drill press, a drill dynamometer with gages, and the recording wattmeter, are shown in Fig. 2. The drill press was a No. 2 manufacturing type Colburn press, which was driven by a 5-hp., 220-volt, 3-phase, 60-cycle motor attached to the rear of the column. The motor drove the tight and loose pulley, through a short belt. A gear pump was provided for raising the coolant, of one part of soluble oil to sixteen parts of water, from the tank in the base of the column to the drill.

The drill dynamometer was of such a design that the torque and thrust could be measured independently. The pressure

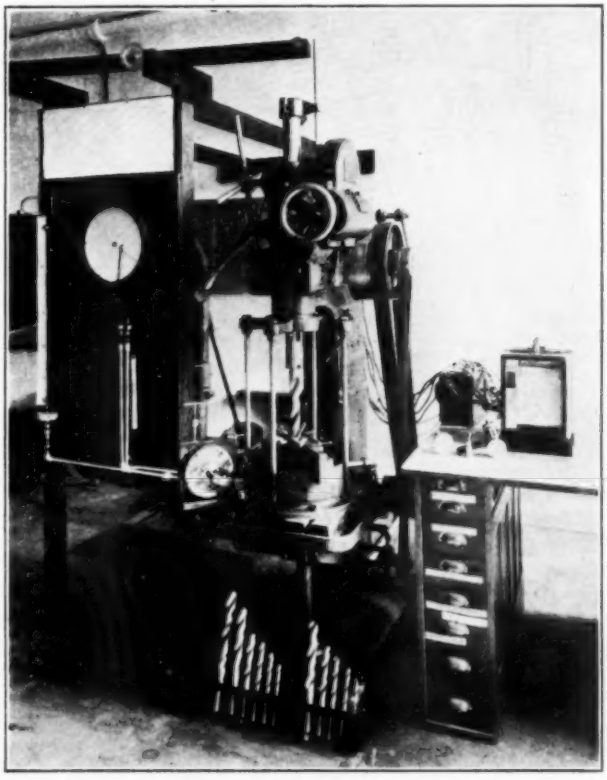

Fig. 2 Drill Press and Equipment Used in Tests

developed by the drill was exerted directly on a plate resting on a rubber diaphragm, just above the dynamometer base. Water underneath this rubber diaphragm was compressed, due to the thrust of the drill, and the pressure was transmitted to one pen of the gage through the 1/8-in. pipe. The plate resting on the rubber diaphragm which carried the thrust load was made to form the lower race of a large ball bearing consisting of sixty-four 1/2-in. balls, so that the table of the dynamometer was free to rotate except for the arm extending to the left, which had a bearing against a piston resting on a second and smaller rubber diaphragm. This arm was one foot long measured from the center of the dynamometer, which corresponded with the center line of the drill spindle. The pressure on this small rubber diaphragm or torque diaphragm compressed water back of the rubber. This pressure was transmitted through a 1/8-in. pipe, leading both to the mercury-column base, and the second pen of the gage. The mercury column had a scale which had units larger (more sensitive) than those of the gage, but which did not have the range permitted by the gage. To prevent tilting of the dynamometer table on the thrust rubber dia-

[3] Selected Bibliography Reference No. 7, p. 38, par. 12, and Figs. 24 and 25.

phragm, a spider fitted around the spindle housing was attached to the table of the dynamometer by four vertical rods. To eliminate friction and to permit the spider to rotate freely with the table as the torque was applied or to be forced downward with the dynamometer table as a thrust was applied, the bearing between the spider and the spindle housing consisted of twenty-four $^1/_2$-in. balls mounted in appropriate races.

The chart of the recording gage was made to rotate, to register the travel of the spindle, by means of a fine wire which passed

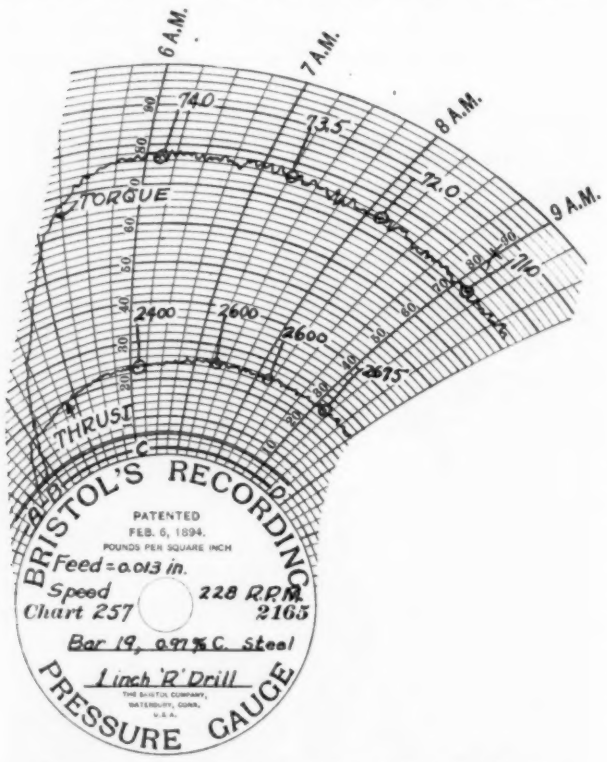

FIG. 3 TYPICAL DRILL TORQUE-AND-THRUST CHART

Mercury-gage reading = 74 to 72
Tight-pulley speed = 618
Actual r.p.m. = 228 × 618/625 = 225.5
Average of four torque readings = 72.63 ft-lb.
Average of four thrust readings = 2569 lb.

from the upper end of the spindle over pulleys to a position vertically above the gage, thence downward, making one turn about a special pulley on the shaft of the gage which carried the chart, to the counterweight shown below the gage.

In calibrating the mercury column and gage for torque in foot-pounds, a couple was applied to the bed of the dynamometer as follows: A 2 in. × 4 in. wood bar was clamped in the vise of the table dynamometer in place of the material to be drilled. This bar extended four feet either way from the center of the drill spindle. Load increments of $^1/_4$ lb. were applied at each end. These loads were suspended by cords over radial ball bearings, so as to transfer the vertical load to one horizontal and at right angles to the ends of the bar. Both horizontal forces acted in a clockwise direction.

Load increments, equivalent to two foot-pounds, were successively added to each end of the bar and corresponding marks, indicating the torque in foot-pounds applied to the dynamometer, were simultaneously made on the mercury-column gage and the recording gage, in order to secure the complete graduated range desired. These marks were made both on increasing and reducing increments of load, so as to allow for any friction which might exist. During this calibration, the spindle of the press was rotated idly by the motor to furnish a slight vibration which would tend to eliminate any friction which might exist in the ball bearings or other parts of the dynamometer. The value of this vibration, however, is somewhat questionable. Various vertical loads up to 3000 lb. were also applied to the dynamometer table during this calibration, but seemed to show no influence on the torque.

The calibration of the recording gage for thrust was obtained by applying various known vertical loads to the spindle. These loads were transmitted through a steel loop-spring placed between the end of the spindle and the table of the dynamometer. The loop spring was supported on knife edges placed in the center of the longer sides. This spring was provided with a dial gage placed across its minor axis so that the load imposed on it could be measured as a function of the deflection. The spring and gage had previously been calibrated on a Reihle universal testing machine. (See Trans. A.S.M.E., 1926, page 755.) As the load was increased by 500-lb. increments corresponding marks were made on the gage chart. After a sufficient number of marks were made on the dial-gage chart for torque and thrust, celluloid scales for torque and thrust were prepared, having the same and smaller graduations. The scale for torque measured $1^5/_8$ in. between the zero and 50-ft-lb. marks, and $3^3/_{16}$ in. between the zero and 90-ft-lb. marks. The thrust scale measured $^{21}/_{32}$ in. between the zero and the 2000-lb. marks, and $^{63}/_{64}$ in. between the zero and the 3000-lb. marks.

Fig. 3 shows a section of a torque and thrust chart from the tests. This is for a one-inch diameter drill cutting tool steel bar 19, at a feed of 0.013 in. and a set-up speed of 228 r.p.m., but an actual speed of 225.5 r.p.m.

After the drill press has been properly set up with the drill and the appropriate speed and feed, the material is adjusted in the vise of the dynamometer. The mercury-column gage is next adjusted for zero reading. At this point, the chart of the pressure gage is rotated so as to draw the base lines for the torque and thrust pens. This insures having the same torque zero reading in all tests, and the exact torque and thrust base lines for each individual test. The drill is brought to within $^3/_8$ in. from the surface of the work to be drilled, after which the feed clutch is engaged. The motor is next started and the belt shifted from the loose pulley to the tight pulley. The drill is thereby rotated and fed toward the work through the $^3/_8$ in. travel, without cutting. During this time the wattmeter is recording the power developed by the motor in driving the machine with all speed and feed gears engaged, but not cutting. At the point A in Fig. 3 the drill has made contact with the work, as is indicated by the increase in the thrust curve. There is no appreciable increase in torque until the drill has penetrated the material to the point B shown on the chart. This distance varies with the drill size. The torque and thrust have reached their full value only when the drill has penetrated to the radial line C shown on the chart. A hole $1^1/_2$ in. deep is drilled between the radial lines C and D. The celluloid scale is used to measure the value of the torque from the base line at four points along the curve of uniform torque. The thrust is similarly measured at four corresponding points. During the drilling, the actual rotating speed of the tight-pulley shaft is measured with a cut-meter, in order that proper allowance may be made for belt slippage, reduced speed of the motor, etc. The nominal speed of the tight-pulley shaft is 625 r.p.m. The motor pulley was made slightly over size, however, so that under no load the tight-pulley shaft rotated at 634 r.p.m. The actual speed of the drill is obtained by multiplying the set-up speed of the drill, by a factor equal to the actual speed divided by the nominal speed, as indicated in Fig. 3, where the average torque, thrust, and r.p.m. developed by the drill are recorded.

The output at the drill point equals the horsepower due to the torque plus that due to the thrust, as follows:

$$\text{output horsepower} = \frac{2\pi \times 72.63 \times 225.5}{33{,}000} + \frac{2569 \times 225.5 \times 0.013}{12 \times 33{,}000} = 3.118 + 0.01905 = 3.13705.$$

The power input to the drill press was determined by attaching to the power line a model LR, AC, S-Polyphase, 60 cycle, 220 volts, clock 73-R, movement 230-p, Esterline-Angus wattmeter. Before use, the wattmeter was carefully calibrated so that the true load in kilowatts developed by the motor could be correlated accurately with the displacement of the pen on the wattmeter chart. The wattmeter chart, paper No. 2310½ C, was two units wide. Each unit was subdivided into tenths of a unit. In order that the calibration made on this paper would be maintained if any other paper were used, a scale was made on cardboard numbered from zero, by tenths, to 2.0, corresponding exactly with the lines of the chart on which the calibration was made. (See Fig. 4.) This cardboard scale was then used to determine the tenths of units deflection of the wattmeter pen on the various wattmeter test charts. The tenths of units were then converted into the true load in kilowatts developed by the motor by another chart which had tenths as abscissas and the kilowatt readings as ordinates with a line drawn from the origin at an angle of approximately 45 deg., in accordance with the calibration.

Fig. 4 shows the chart from the wattmeter as recorded at the time the torque-and-thrust chart was made. The motor is started at C and the belt is thrown from the loose to the tight pulley so that the chart reading at A represents the power developed by the motor in running the press idly during the ³/₈-in. drill travel, before starting to cut. This is called the tare reading. When the drill starts to cut, the power increases, and an average value is taken at B. Below the chart in Fig. 4 is shown the scale used for obtaining the readings from the wattmeter charts.

The gross power equals XB = 0.70 unit = 3.67 kw.
The tare power equals XA = 0.09 unit = 0.502 kw.
The net power equals AB = 3.670 — 0.502 = 3.168 kw. = 4.245 hp.

From the torque-and-thrust values of Fig. 3, the power output was found to be 3.137 hp., and from the wattmeter chart of Fig. 4 the net input was found to be 4.245 hp. The efficiency, then, with the particular gears used is 3.137 divided by 4.245 = 74.8 per cent. This efficiency indicates the difference in friction in the various parts of the mechanism when running idly and under power. This efficiency will vary slightly, for the different ratios of pick-off speed and feed gears, and the ratio of the back gears used. The efficiency of the operation considering the total or gross input of 3.67 kw. or 4.918 hp. is 63.8 per cent.

Speeds and Feeds Used

The feeds used were selected from the tables of speeds and feeds for high-speed-steel drills, on page 233 of the National Twist Drill and Tool Company, catalog No. 14. The values selected, as shown in Table 5, compare favorably with those given in most other tables of this type, and are believed to represent good practice, based on years of experience. The feeds as given had to be modified in some instances because those specified were not available through the change gears of the drill press used in the experiments, so that the nearest feed available was substituted. It is realized that in some plants, or individual operations, lower feeds with speeds above normal are used. Again, feeds heavier than those specified may be used with speeds above or below those recommended by common practice to suit various requirements or conditions, such as the finish or accuracy of alignment required, the depth of the hole to be drilled, the material being drilled, the kind of cutting fluid used, if any, the kind and condition of the drilling machine, etc. To anticipate such variations over a limited range, a series of tests were first run with the ¹/₄-, 1-, and 1¹/₄-in. diameter drills in steel and cast iron, with feeds ranging from 0.006 to 0.021 in. per revolution for each drill size and material.

It was originally the intention of the authors to run tests as near as possible to those specified for each material in the usual speed and feed table. It was obvious that with the larger drills and their heavy feeds, the power would be so much larger than for small drills, that different rheostat settings for the wattmeter would have to be used in order to get charts on the same scale large enough to read without serious error for the small power values, and yet not too large for the large values. From preliminary tests made to determine the influence of speed on the torque and thrust, it was concluded that while power increased in direct proportion to the speed, the torque and thrust were each quite constant for a given drill diameter and feed, over the whole range of speeds available. Also, the five horsepower motor attached to the drill press used in these experiments, did not have sufficient capacity to drive the larger drills with their corresponding heavy feeds at appropriate commercial speeds.

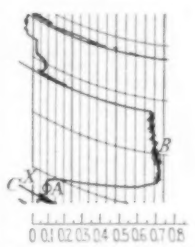

Fig. 4 Wattmeter Chart Corresponding to the Torque-and-Thrust Chart Shown in Fig. 3

Knowing the torque, thrust, and feed for any test, the power output at the drill point can be determined readily for any desired speed. By dividing its calculated net-power-output by the efficiency of the motor and press, the input is obtained. For commercial tests, therefore, a cutting speed of 60 ft. per min. was selected. The r.p.m. for the surface speed of 60 ft. per min. for each drill size, and the r.p.m. for which speed gears were available as near these values as possible, are given in Table 5. In every test, the actual speed was observed by the cut meter, so as to account for belt slippage in the final calculations of power developed at the point of the drill.

A coolant was used in all of the tests, which consisted of one part of soluble oil to 16 parts of water. This was renewed frequently during the tests so that its properties would remain as constant as possible.

Results of Tests

The experiments run to determine the power required to drill cast iron and steel were conducted under two main headings: commercial and special. The commercial tests were conducted so as to determine the torque, thrust, horsepower input and output for each drill diameter operating at a peripheral speed of 60 ft. per min., and at a feed which is considered good for commercial practice. The speeds and feeds for the various drills are given in Table 5. The second set of experiments under the heading of special tests were run to determine the influence of each particular variable such as the drill size, feed, and speed, in the hopes that satisfactory values might be determined for the torque, thrust, or power developed for any drill diameter at any speed and feed.

The Commercial Drilling Test

A summary of the data obtained in drilling bar 3, S.A.E. 2320 steel, with all available drill sizes at a speed of approximately

60 ft. per min. and the commercial feeds, is given in Table 6. The average torque in foot-pounds is recorded for each drill size and feed together with its equivalent in computed horsepower. The thrust for each drill size and feed is also given, together with its computed horsepower for the speed and feed recorded. The total horsepower output developed at the drill point, which equals the horsepower due to the torque plus that due to the thrust, is shown. The net input developed by the motor is shown in both kilowatts and equivalent horsepower. This net input equals the gross power developed minus the tare or that power developed by the motor to drive the drill press with the speed and feed gears engaged, but with the drill not cutting. Finally, the efficiency of the press is shown and is

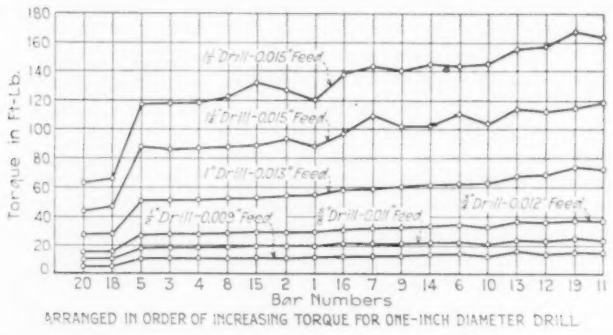

FIG. 5 TORQUE VALUES FOR EACH DRILL DIAMETER AND ITS COMMERCIAL FEED FOR ALL MATERIALS

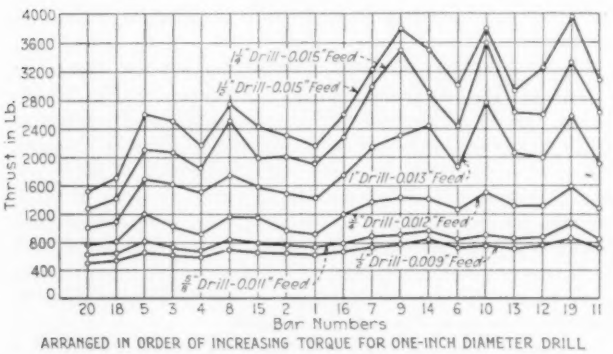

FIG. 6 THRUST VALUES FOR EACH DRILL DIAMETER AND ITS COMMERCIAL FEED FOR ALL MATERIALS

as of the loads carried by them. The fact that these efficiencies do not vary uniformly from the maximum for the smallest drill, to the minimum for the largest drill, is believed to be due to the ratio of the speed and feed change gears, and the ratio of the back gears used for each particular test.

Figs. 5, 6, and 7 show the torque, thrust, and net horsepower input values, respectively, plotted over the bar numbers arranged in order of increasing torque for the 1-in. diameter drill. The torque values as shown in Fig. 5 for each drill size and commerical feed indicated an increase, in general, from the left to the right, following the 1-in. drill torque curve rather satisfactorily. The values for bar 10, for the $^1/_2$-, $^5/_8$-, $^3/_4$-, and $1^1/_4$-in. diameter drills are low, however, and indicate that bar 10 properly belongs farther to the left. Also, the values for the $1^1/_4$-in. and $1^1/_2$-in. drills appear to vary more than those for the other drill sizes; the values for bar 1 are particularly low for the two largest drills. No explanation can be given for such irregularities unless they are due to variations in the properties of the material at the particular points drilled.

The thrust values, as shown in Fig. 6, vary considerably more throughout each curve than the torque values do. This variation is believed to be the result of differences in the material,

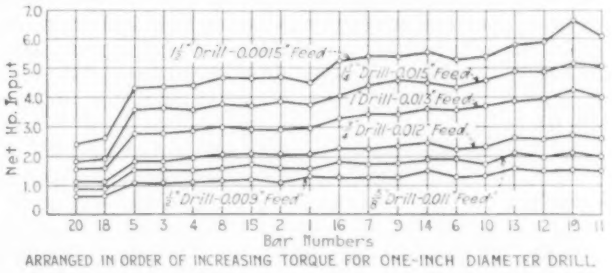

FIG. 7 NET HORSEPOWER INPUT VALUES FOR EACH DRILL DIAMETER AND ITS COMMERCIAL FEED FOR ALL MATERIALS

or due to the variation in the length of the chisel edge of the drill as the web thickness increases through repeated grinds. This increase in web thickness, from that of the new drill to that after the last grind is shown in Table 2, and is greatest for the largest drills. This total variation, however, did not occur during the running of these commercial tests, and so can be held responsible for only a small share. While the variation in the thrust curves is disconcerting when the loads on the drill or spindle bearings and gears are concerned, it is of little importance as far as power is concerned, inasmuch as the thrust by itself contributes less than 1 to 2 per cent of the total computed power.

TABLE 6 SUMMARY OF RESULTS OF THE COMMERCIAL DRILLING TESTS FOR ALL DRILL SIZES ON BAR 3 STEEL S.A.E. 2320

Drill size	R.p.m. Set-up	R.p.m. Factor	R.p.m. Actual	Feed, in. per rev.	Torque in ft-pounds	Torque hp. = 0.0001904 $N\,T$	Thrust in lb. $1^1/_2$	153	$\frac{618}{625}$	151.2	0.015	118	3.40	2506.25	0.01434	3.543	3.254	4.36	81.3

equal to the computed horsepower output divided by the horsepower input. As is usual in all of these tests, the efficiency is highest for the smallest drill rotating at the greatest r.p.m., and is lowest for the largest drill which rotates at the slowest r.p.m. It appears, therefore, that the efficiency is not so much the function of the speed at which the gears and bearings rotate

The net horsepower input values for each drill diameter operating at its commercial feed and a speed of approximately 60 ft. per min. are shown in Fig. 7. This net horsepower was determined from the wattmeter charts, and is the equivalent of

the gross power minus the tare. The tare value varies considerably for the different speeds used, and is much greater for the $^1/_2$-in. drill than for the $1^1/_2$-in. drill. The influence of the different feed gears used, however, is hardly perceptible, as the rise in the curve when the feed gears are engaged is not more than the thickness of the line on the chart. It was, therefore, thought desirable to present these net values rather than the gross values as they may be compared directly. These input values follow quite satisfactorily the general trend of the torque curves shown in Fig. 5.

The complete drilling story for the commercial drilling tests on six materials, bars 20, 5, 1, 7, 10, and 19, selected at random throughout the material range, are shown in Figs. 8 to 13, inclusive. Fig. 8, for example, shows for bar 20, cast iron containing 20 per cent charcoal pig, the torque in foot-pounds, the thrust in pounds, the net power input in horsepower determined from the wattmeter chart, and the computed horsepower output at the drill point for each size at its appropriate speed and feed shown in Table 5.

It should be noted that the abscissas consist of two variables, the drill diameter and the feed, so that there is no particular reason why these torque or thrust curves should be smooth curves. From the $^1/_2$-in. drill to the $^5/_8$-in. drill, the diameter increment is $^1/_8$ in., while the feed increment is 0.002 in. For the $^1/_8$-in. diameter increment between the $^5/_8$-in. and $^3/_4$-in. drills, the feed increase is only 0.001 in. For the $^1/_4$-in. increase in diameter between the $^3/_4$-in. drill and 1-in. drill, the feed increase is only 0.001 in. The $1^1/_4$-in. and $1^1/_2$-in. drills operate at the same feed.

The torque, thrust, input, and output horsepower curves are shown for bar 5, S.A.E. 3135 steel, in Fig. 9. The general characteristics of the curves are similar to those of Fig. 8 for cast iron. In Fig. 8 the thrust value for the $1^1/_4$-in. diameter drill appears to be somewhat low in order to obtain a smooth curve concave downward. In Fig. 9 the thrust values for the $^5/_8$-in. drill appear to be a little low for a similar curve concave downward. The torque curves in Figs. 8 to 13, inclusive, appear to be rather smooth curves slightly concave upward. In all

The Special Drilling Tests

In order to throw more light on the influence of the drill diameter, the feed in inches per revolution, and the speed of rotation, a number of special tests were run in which but one of these factors was varied at a time. It was hoped that by knowing the influence of each one of these variables, the data from the commercial tests as presented in Figs. 5 to 13, inclusive, and Table 7, could be extended to cover almost any combination of drill diameter, speed, and feed. The tests were run with a soluble oil mixed with 16 parts of water; the same as used in the commercial tests.

Variable Speed Tests were run with speeds of 74, 153, 230, 296, 360, and 441 r.p.m. on steel and cast iron with $^1/_2$-, 1-, and $1^1/_4$-in. diameter drills at a feed in each case of 0.012 in. In Fig. 14 are given the results of the tests with the six different speeds ranging from 74 to 441 r.p.m. for a $^1/_2$-in. diameter drill on bar 6, S.A.E. 6150 steel, and a cast-iron bar 20 (20 per cent charcoal pig, dated 4–8–28), not listed in Table 1 but similar to bar 18. The feed for the $^1/_2$-in. drill was 0.012 in. per revolution. The torque for steel, shown in solid lines, is practically constant at $17^1/_2$ foot-pounds for speeds of 441, 360, and 296

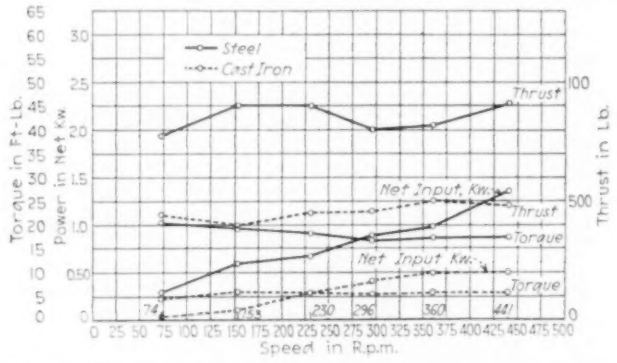

Fig. 14 Variable-Speed Tests Showing Torque, Thrust, and Net-Input Kilowatts for Steel Bar 6 (S.A.E. 6150) and Cast-Iron Bar 20, 4–8–28 (20 Per Cent Charcoal Pig) With Constant Feed of 0.012 Inch per Revolution—Diameter of Drill $^1/_2$ Inch "R"

r.p.m., but then increases gradually to 20 foot-pounds when the speed is reduced to 74 r.p.m. The torque values for cast iron, shown in dashed lines, are practically constant at 6.3 foot-pounds at all speeds except 74 for which the torque is only 4.5 foot-pounds. It is also to be seen that the torque for the steel is 2.78 times that for the cast iron. From these data, it may be concluded that the torque is not a function of the revolutions of the drill, but is constant over the range covered.

The thrust curves for both the cast iron and steel vary slightly for different speeds. This variation is thought to be due to the material, or condition of the drill, rather than to the variation in speed. The input in kilowatts for both the steel and cast iron as determined by the wattmeter also appears to be a straight-line function, although some points do not fall exactly on this straight line. In all cases exact experimental results are shown rather than smoothed-out values.

Variable-speed tests for the 1-in. diameter drill at a constant feed of 0.012 in. per revolution for steel bar 6 and cast-iron bar 20 (4–8–28), are shown in Fig. 15. The materials are the same as those used in the tests reported in Fig. 14. The torque curve for steel appears to be horizontal except for the high value of 63 foot-pounds at the lowest speed of 74 r.p.m. This was checked three times and the same values obtained each time. The other values, however, appear to be practically constant at about 58.5 foot-pounds. The torque curve for cast iron appears to be practically horizontal, i.e., at 25 foot-pounds for the intermediate speeds, but slightly low for the lowest and highest speeds. The thrust values for both the cast iron and steel appear to be such that, allowing for the slight variations due to

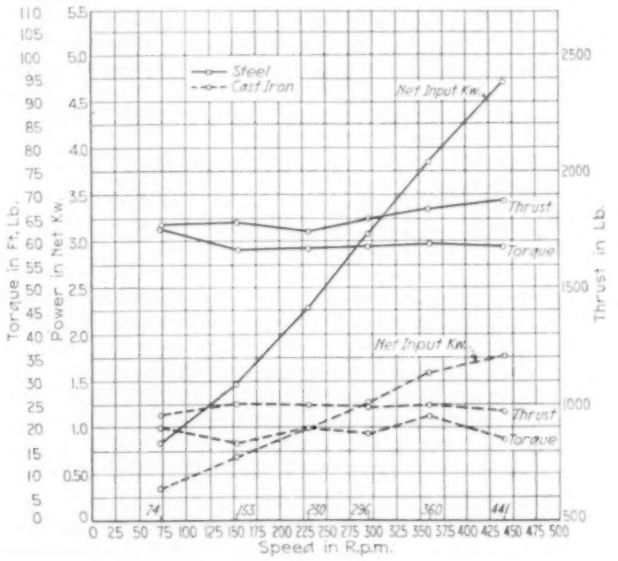

Fig. 15 Variable-Speed Tests Showing Torque, Thrust, and Net-Input Kilowatts for Steel Bar 6 (S.A.E. 6150) and Cast-Iron Bar 20, 4–8–28 (20 Per Cent Charcoal Pig) With Constant Feed of 0.012 Inch per Revolution—Diameter of Drill One Inch "R"

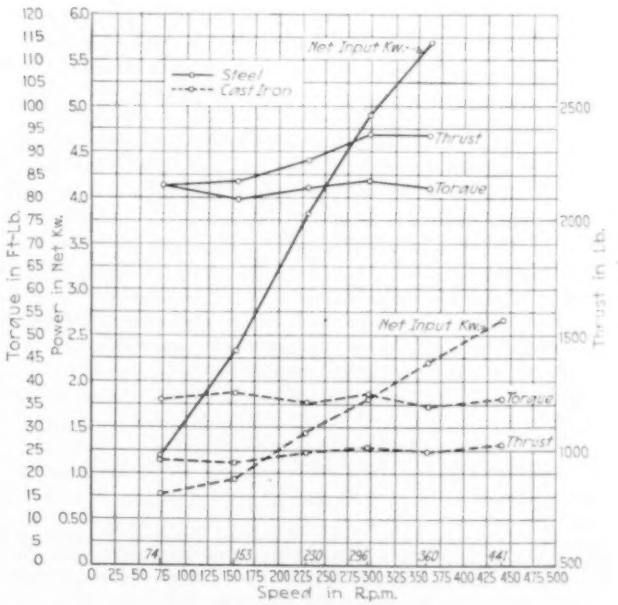

Fig. 16 Variable-Speed Tests Showing Torque, Thrust, and Net-Input Kilowatts for Steel Bar IIIIII (0.15 Per Cent C) and Cast-Iron Bar 25, 4–8–28 (20 Per Cent Charcoal Pig) With Constant Feed of 0.012 Inch per Revolution-Diameter of Drill $1^1/_4$ Inch "R"

experimental error and variation in material, it may be concluded that the thrust is not a function of the speed but constant over the whole range of speeds covered. The net input in kilowatts as determined by the wattmeter appears to vary directly with the speed.

Fig. 16 shows another series of tests on a 0.15 per cent carbon open-hearth steel bar IIIIII, and cast-iron bar 25 (20 per cent charcoal pig dated 4–28–8) for a drill diameter of $1^1/_4$ in. and a feed of 0.012 in. per revolution. The torque values for both the cast iron and steel are practically constant over the whole speed range. The thrust values for cast iron are practically constant, but those for steel appear to increase from 2150 lb. at 74 r.p.m. to 2370 lb. for 360 r.p.m. This increase, while uniform, would

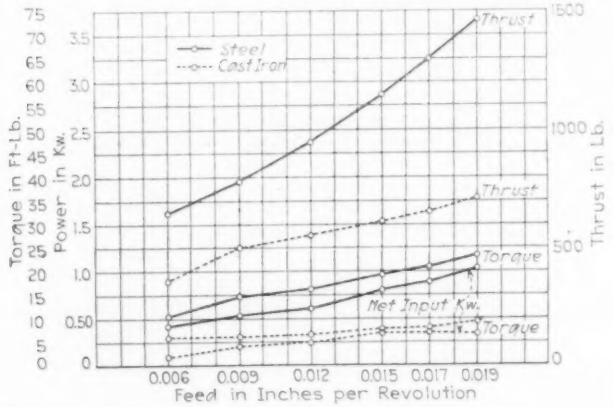

Fig. 17 Variable-Feed Tests Showing Torque, Thrust, and Input Kilowatts for Steel Bar 6 (S.A.E. 6150) and Cast-Iron Bar 20 (20 Per Cent Charcoal Pig) With Constant Speed of 230 R.p.m.—Diameter of Drill $^1/_2$ Inch "R"

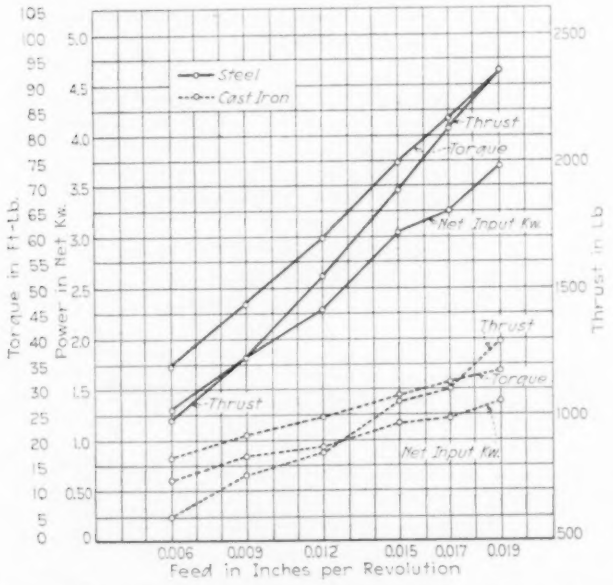

Fig. 18 Variable-Feed Tests Showing Torque, Thrust, and Net Input Kilowatts for Steel Bar 6 (S.A.E. 6150) and Cast-Iron Bar 20 (20 Per Cent Charcoal Pig) With Constant Speed of 230 R.p.m.—Diameter of Drill One Inch "R"

indicate that the thrust increases with the speed. In view of the slight increase, however, and the results of the previous tests, it is concluded that the thrust is practically constant over the whole speed range.

Variable Speed Tests—Results of Other Experimenters

Benedict and Lukens[4] conclude that when drilling cast iron with a 1-in. diameter drill having a clearance of 7 deg. and a point angle of 118 deg., the torque decreases as the speed increases for a given feed per revolution, although in most cases no decrease in torque appears for speeds greater than 400 r.p.m. The results are not uniform for speeds less than 150 r.p.m. In nearly all tests this decrease in torque was noted, particularly when the drill was a trifle dull. Eight feeds from 0.00364 to 0.041 in. per revolution were used. An analysis of these curves indicates that for all feeds of 0.0256 in. and less, the torque curve is really horizontal for speeds of 570 r.p.m. down to 200, and again horizontal but slightly higher for speeds of 150 r.p.m. down to 60 r.p.m. For the feed of 0.041 in. the torque curve is smooth, and decreases quite uniformly as the speed is increased. The thrust values from these same tests by Benedict show the

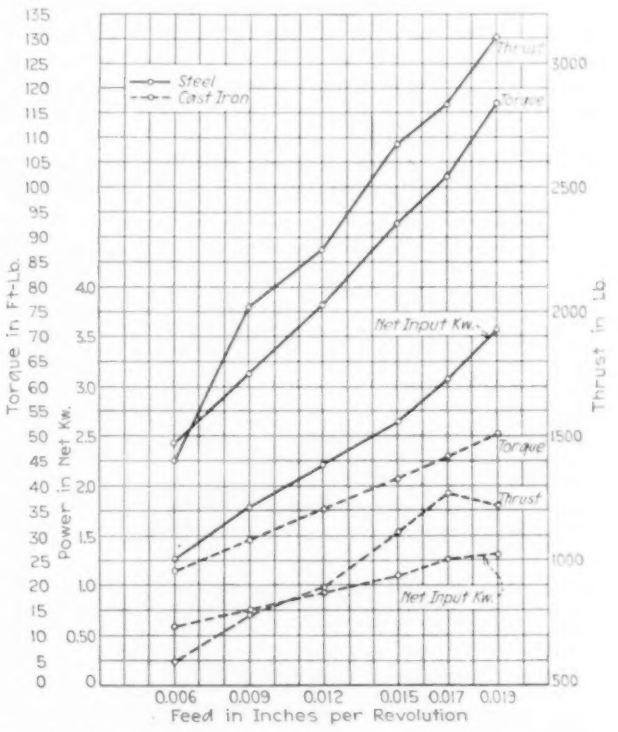

Fig. 19 Variable-Feed Tests Showing Torque, Thrust, and Net Input Kilowatts for Steel Bar IIIIII (0.15 Per Cent C) and Cast-Iron Bar 25 (20 Per Cent Charcoal Pig) With Constant Speed of 153 R.p.m.—Diameter of Drill $1^1/_4$ Inch "R"

same general characteristics as for the torque, except that straight lines have been drawn to represent the smooth curve instead of the slightly concave-upward curve for the torque values. The thrust for the feed of 0.00364 in. per revolution is horizontal, but a slope upward to the left for reduced speeds is noticeable for the feed of 0.0056 in. This slope increases with the feed until, for the 0.041 in. per revolution feed, the thrust of 1910 lb. for the speed of 570 r.p.m. is increased 16.6 per cent to 2230 for 60 r.p.m.

H. M. Norris[5] concluded that when the diameter of the drill and rate of feed are constant, the power required to cut a given metal is approximately proportional to the speed.

Bird and Fairfield[6] report that no material difference either in torque or thrust was found by increasing the speed from 140 to 600 r.p.m. when drilling soft gray iron. A $^5/_8$-in. diameter high-speed-steel twist drill was used which had an included point angle of 118 deg.

[4] Ref. 7 in Bibliography, p. 53 and Figs. 32 and 33.

[5] Ref. 2 of Bibliography, p. 75.

[6] Ref. 3 of Bibliography.

Smith and Poliakoff[7] also report that there was no perceptible difference in the torque or thrust with the variation of speed, that is, the net computed horsepower for a given diameter of drill and feed when cutting cast iron or steel is proportional to the revolutions or the cutting speed. Their tests were comprehensive but the speeds were between 5 and 150 r.p.m.

Variable Feed Tests

The results of several tests to show the influence of changing feed on the torque, thrust, and net input in kilowatts for two steels and two cast irons are shown in Figs. 17, 18, and 19. The feeds were varied from 0.006 in. per revolution of the drill to 0.019 in. The results for the $^1/_2$-in. diameter R drill are shown in Fig. 17. The solid lines indicate the thrust, torque, and net input in kilowatts for steel bar 6 (S.A.E. 6150) as reported on in the commercial test, and the dashed lines indicate the values for cast-iron bar 20. (20 per cent charcoal pig, dated 4–8–28.) The speed was constant at 230 r.p.m. The thrust curve for steel shows a steady increase as the feed is increased, and it is slightly concave upward. The curve would have to turn concave downward below the feed of 0.006 in. in order to pass through the origin. This indicates that the thrust curve really should be concave downward all the way rather than as shown. The first 0.006-in. feed from zero gives a thrust of 650 lb. The second 0.006-in. feed (up to 0.012 in.) increases the thrust only 300 lb. to 950 or 46.2 per cent. The third 0.006-in. increase in feed above 0.012 in., causes an increase in thrust of 430 lb. to 1380 lb. for a feed of 0.018 in. In other words, the thrust for a feed of 0.006 in. is 650 lb. while the thrust for 0.018-in. feed is only 1380 lb., or an increase of 112 per cent thrust for the 200 per cent increase in feed. The thrust curve for cast iron, on the other hand, is practically a straight line except for the low value at 0.006-in. feed, which increases in direct proportion to the increase in feed. This curve also would have to continue concave downward to the left in order to pass through the origin, which shows that the thrust for cast iron increases with the feed but at a slower rate. The torque curves for steel and cast iron are also approximately straight lines for the feed range shown, but both would have to turn downward if continued to the left, in order to pass through the origin. The torque value for steel for the feed of 0.009 in. appears to be a little high as is that for cast iron at 0.006-in. feed.

In Fig. 18 are shown the torque, thrust, and net input in kilowatts for the 1-in. R drill rotated at 230 r.p.m. on bar 6, S.A.E. 6150 steel, and cast-iron bar 20. (20 per cent charcoal pig, dated 4–8–28.) Again, the torque curves for both the steel and cast iron are practically straight lines for the range of feeds covered, and both would have to turn downward to the left to pass through the origin. The thrust curves also are practically straight lines, both being slightly concave upward but would have to drop at the left to pass through the origin.

In Fig. 19 are shown the torque, thrust, and net input in kilowatts for steel bar IIIIII (0.15 per cent carbon) and cast-iron bar 25 (20 per cent charcoal pig) for the $1^1/_4$-in. diameter R drill at a constant speed of 153 r.p.m. Again, the two torque curves appear to be practically straight lines for the feed range covered, but are high and would have to turn downward to the left to pass through the origin. The thrust curve for steel is practically a straight line between the feeds of 0.009 and 0.019 in.; the value for the feed of 0.006 in., however, falls below the straight line, and tends to swing the line downward toward the origin. The thrust curve for cast iron is not far from a straight line if the low value for the feed of 0.019 in. is disregarded, but also must turn downward at the left to pass through the origin.

As a conclusion for the influence of the variable feed on the torque and thrust for the $^1/_2$-, 1- and $1^1/_4$-in. diameter drills on steel and cast iron it may be said that the torque on cast iron for all three drill sizes is a straight line, but for steel the torque curve is slightly concave upward for each drill size. It is believed that it should be concave downward. All torque curves must become concave downward if continued to the left in order to pass through the origin. The thrust curves for all three drill sizes on cast iron are straight lines while those on steel are slightly concave upward, except for the $1^1/_4$-in. drill, which is straight. These, too, must turn downward to pass through the origin.

Better to visualize the influence of the feed on the torque and thrust values presented in Figs. 17, 18, and 19 for two steels and two cast irons, the torque and thrust curves were all plotted on log-log paper and their slopes n determined as follows:

For steel bar 6 with the $^1/_2$-in. drill, for bar 6 with the 1-in. drill, and for bar IIIIII with the $1^1/_4$-in. drill, n was found to be 0.722, 0.841, and 0.784, respectively, averaging 0.782, for the torque curves.

For cast-iron bar 20, with the $^1/_2$-in. drill, for bar 20 with the 1-in. drill, and bar 25 with the $1^1/_4$-in. drill, n was found to be 0.547, 0.60, and 0.669, respectively, averaging 0.605 for the torque curves. Similar values of n for the thrust for the steels in the order named above are: 0.809, 0.860, and 0.681, averaging 0.783. The values of n for the thrust curves on the cast iron in the order named were found to be 0.516, 0.580, and 0.710, respectively, averaging 0.602.

It is seen that there is a considerable variation as to the slope of the curves for the same material with different drill sizes, as well as between different materials, so that the variation noted may be due to lack of uniformity in experimental results, or due to the specific material and cutting condition. Not enough information is available to draw definite conclusions on this point at the present time so that the average values will be accepted for the present.

Variable Feed Tests—Results of Other Experimenters

Benedict and Lukens[8] report that "in soft cast iron the torque does not increase so rapidly as the feed per revolution, although variation of torque with feed is so nearly direct that it may for all practical purposes be so considered. For the correct angles of drill grinding, the thrust should increase directly with the feed per revolution. In soft cast iron the torque decreases as the speed increases, although there is little advantage in running a 1-in. drill faster than 450 r.p.m. The saving in power resulting from increasing the speed may amount to 10 or 15 per cent. Thrust decreases as speed increases for corresponding rates of feed, although the advantages to be gained by running a 1-in. diameter drill faster than 400 r.p.m. are slight. The decrease in thrust may amount to 15 per cent."

A 1-in. diameter drill having a clearance of 7 deg. and a point angle of 118 deg. was used on cast iron at feeds ranging from 0.00364 to 0.041 in. per revolution at each of the three speeds of 92, 233, and 456 r.p.m. The torque curves are practically straight lines but slightly concave downward, while the thrust curves are practically straight but slightly concave upward. The torque curves would have to drop sharply at feeds below the smallest used in order to pass through the origin.

Smith and Poliakoff[9] conclude from their extensive experiments that for cast iron the torque does not increase as fast as the feed for any given diameter of drill. Thus, $T = 785\, d^{1.82}\, t^{0.72 - 0.0005d}$ or as a close approximation $T = 740\, d^{1.8}\, t^{0.7}$, in which T = torque in foot-pounds, d = drill diameter in inches, and t = feed in inches per revolution. The following linear

[7] Ref. 4 of Bibliography, Part 1, p. 323 and 378.

[8] Ref. 7 of Bibliography, p. 92, pp. 48–53, Figs. 30 and 31.

[9] Ref. 4 of Bibliography, pp. 339, 379, and 380.

expression is a further approximation and may be preferred to the exponential given above, $T = 10d^2 + (14d^2 + 3)100t$, or, as a further simplification, $T = 14d^2(1 + 100t)$ is given.

The tests for thrust on cast iron show a lack of consistency in spite of the fact that every care was taken. The thrust values for each drill size were plotted over the feed, and are represented graphically as straight lines which do not pass through the origin. A general expression for thrust in cast

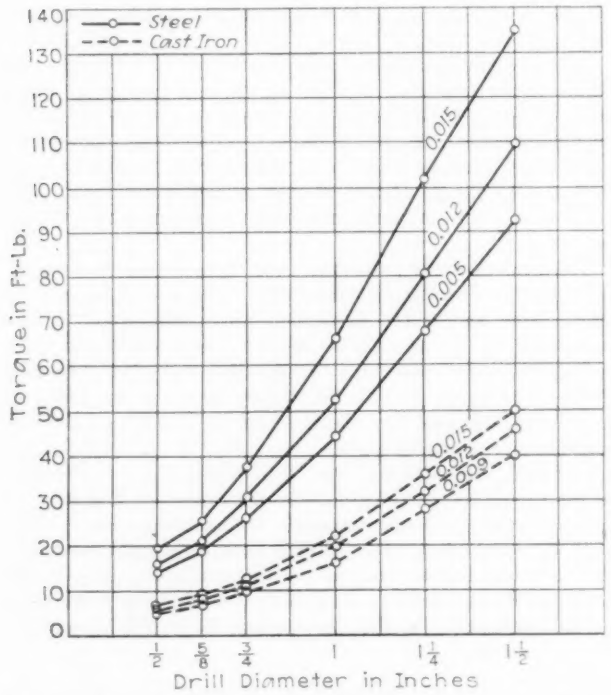

FIG. 20 VARIABLE DIAMETER TESTS SHOWING TORQUE FOR STEEL BAR IIIIII (0.15 PER CENT C) AND CAST-IRON BAR 8A (20 PER CENT CHARCOAL PIG)—FEEDS AT 0.009, 0.012, AND 0.015 INCH PER REVOLUTION—SPEED CONSTANT AT 230 R.P.M.

iron was developed, as follows: $Th = (d - 0.4)325 + (24d + 65)1000t$, in which Th = Thrust, d = drill diameter in inches, and t = feed in inches. This is more simply and approximately expressed by $Th = 240d + (24d + 65)1000t$, and for some purposes it may be good enough to take $Th = 200d + 10{,}000t$, which is roughly correct. The general expression for thrust is simplified to $P = 52{,}900\, t^{0.92 - 0.087d}$, which agrees with $P = 35{,}500\, d^{0.7} t^{0.75}$, as the latter is likely to prove most serviceable to the practitioner.

Similar equations are developed by Smith and Poliakoff for medium-hard steel, as follows: The general law for various drill diameters and feeds is $T = 2350\, d^{1.28} t^{1/5} d^{-0.64}$, T = torque in foot-pounds, d = drill diameter in inches, and t = the feed in inches per revolution. The general straight-line law is $T = 18d^2 + 100t(27d^2 + 20)$ but the approximate general law is $T = 1640\, d^{1.8} t^{0.7}$.

For thrust in medium hard steel the approximate general law is $P = 33{,}500\, d^{0.7} t^{0.6}$, in which P is the thrust in pounds.

Smith and Poliakoff conclude (Part II) as to the influence of feed on torque and thrust as follows:

"The net horsepower per cubic inch of metal removed is inversely proportional to $d^{0.2} t^{0.3}$ and independent of the revolutions. Thus the net horsepower per cubic inch of metal =

$$\frac{4 \times 2\pi N c d^{1.8} t^{0.7}}{33{,}000\, \pi d^2 t N} = \frac{k}{d^{0.2} t^{0.3}}$$ where c and k are constants.

"If the diameter of the drill remains constant and feeds of $^1/_{400}$ in., $^1/_{100}$ in., and $^1/_{25}$ in. are taken, the corresponding horsepowers will be in the order of 1, 0.66, and 0.435 which is in the order of the cutting pressures given on pages 343 and 345. If t remains constant and values of $d = ^1/_2$ in., 2 in., and 4 in. are taken, then the horsepower for each successive drill will be in the order of 1, 0.76, and 0.66 in."

"The end thrust when operating on cast iron or steel does not increase in proportion to the feed for a given diameter of drill or in proportion to the diameter for a given feed."

Both the torque and thrust curves for cast iron and medium-hard steel are therefore straight or slightly concave downward which does not agree in all instances with the authors.

The torque curve for the $^5/_8$-in. diameter drill cutting at a speed of 420 r.p.m. and various feeds from 0.004 to 0.020 in., as given by Bird and Fairfield[10] is concave downward, but the thrust curve appears to be excessively concave upward.

The tests on cast iron by H. M. Norris[11] show that for drills from $^1/_2$ in. to $1^1/_2$ in. in diameter when operating at feeds between 0.015 and 0.035 in. per revolution, the gross horsepower

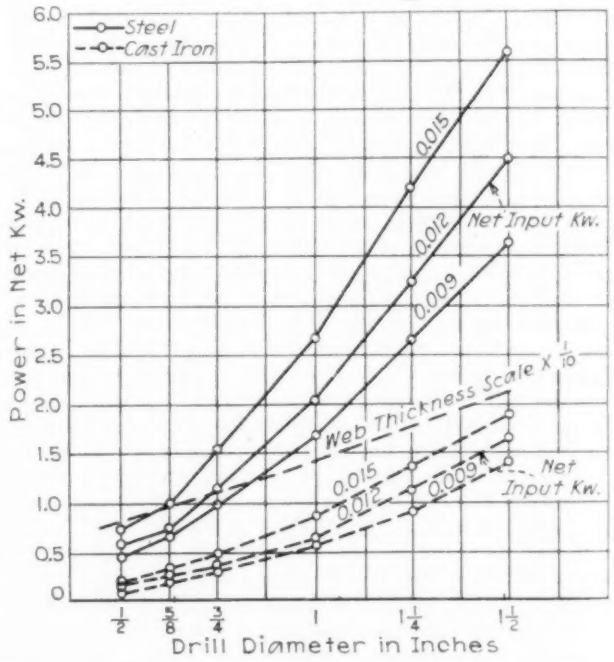

FIG. 21 VARIABLE DIAMETER TESTS SHOWING NET INPUT KILOWATTS FOR STEEL BAR IIIIII (0.15 PER CENT C) AND CAST-IRON BAR 8A (20 PER CENT CHARCOAL PIG)—FEED CONSTANT AT 0.009, 0.012, AND 0.015 INCH PER REVOLUTION—SPEED CONSTANT AT 230 R.P.M.

input varies practically as a straight line, although it is slightly concave upward for the lower values of feed. The horsepower per cubic inch of metal removed per minute is highest for the low feeds, and reduces gradually as the feed is increased, giving curves almost horizontal for the $1^1/_2$-in. diameter drill, but distinctly concave upward, and higher for the lower feed values for the $^1/_2$-in. diameter drills.

VARIABLE DIAMETER TESTS

The results of several tests to show the influence of the diameter on the torque for feeds of 0.009, 0.012, and 0.015 in. per revolution for all drill sizes from $^1/_2$ in. to $1^1/_2$ in. in diameter

are shown in Figs. 20 and 21. Again, the set of R drills were used. The tests were conducted on an open-hearth steel bar IIIIII (0.15 per cent carbon), and a cast-iron bar 8-A which was made up of 20 per cent charcoal pig, similar to bar 20 used in the variable-feed tests, and bar 18 in the commercial tests.

The values of the torque in foot-pounds for the steel and cast iron at the three different feeds are shown in Fig. 20. The values for each curve were determined at times several weeks apart, so that the web thickness of each drill may have varied slightly. For all feeds, on both steel and cast iron, smooth curves are obtained. The torque increases rapidly as the diameter of drills is increased.

The net input in kilowatts as determined by the wattmeter for the torque tests is shown in Fig. 21. These values correspond favorably with the values of the torque shown in Fig. 20.

The values shown in Figs. 20 and 21 are not only functions of the outside diameter of the drills, but of the particular geometric shape and size of each drill considering such items as the web thickness, shape and helix of the flute, chisel-edge angle, etc. The slight variation in the web thickness will undoubtedly influence these values considerably. Better to visualize the values of the web thickness of the drills after they have been ground a number of times, as taken from Table 1, and to compare the values of drills of different sizes, they are shown graphically in Fig. 21. The ratio of the web thickness to the diameter for the 1/2-, 5/8-, 3/4-, 1-, 1 1/4-, and 1 1/2-in. drills is 0.166, 0.15, 0.143, 0.14, 0.139, and 0.142, respectivley, showing that the web thickness is greatest in proportion to the diameter for the smallest drills.

The values of the thrust for the different drills of Figs. 20 and 21 were rather widely spaced. The general trend, however, of these curves is to increase in direct proportion to the drill diameter.

A second set of tests were run to determine the influence of the variable diameter on steel bar 6, S.A.E. 6150, and cast-iron bar 20 (20 per cent charcoal pig, dated 4–8–28) at a constant speed of 230 r.p.m. and a feed of 0.015 in. per revolution. These values are shown plotted in Fig. 22. The thrust curve for steel is practically straight up to the 1 1/4-in. diameter drill. The value for the 1 1/2-in. diameter drill is obviously low. The thrust curve for cast iron while slightly variable is also practically straight. Both thrust curves if continued to the left would pass through the origin.

The torque curves for both steel and cast iron are concave upward, and would obviously pass through the origin if continued to the left. The net input in kilowatts is also shown for cast iron and steel.

In order to determine more carefully the influence of the diameter on the torque and thrust the three torque curves of Fig. 20 for steel bar IIIIII (0.15 per cent carbon), and the torque curve of Fig. 22 for steel bar 6, were plotted on log-log paper. Four straight lines were obtained, the slopes n of which were as follows:

Bar 6 (S.A.E. 6150) at a feed of 0.015 in..... $n = 1.79$
Bar IIIIII (0.15 per cent carbon) feed 0.015 in..... $n = 1.93$
Bar IIIIII (0.15 per cent carbon) feed 0.012 in..... $n = 1.81$
Bar IIIIII (0.15 per cent carbon) feed 0.009 in..... $n = 1.805$

Similarly the three torque curves of Fig. 20 for cast-iron bar 8 A, and the torque curve of Fig. 22 for cast-iron bar 20 were plotted on log-log paper and the following values obtained:

Bar 8 A at a feed of 0.015 in..... $n = 1.97$
Bar 8 A at a feed of 0.012 in..... $n = 1.98$
Bar 8 A at a feed of 0.009 in..... $n = 2.0$
Bar 20 at a feed of 0.015 in..... $n = 1.97$

It may be that the exponents of the drill diameter d are different for steel for different rates of feed, but the fact that they are so close for the range in feeds given for bar IIIIII may indicate that 1.8 is a good average value. It is interesting to note that n for bar 6 at 0.015-in. feed conforms to the value of n for bar IIIIII at 0.009 in. and 0.012-in. feed, but that n for bar IIIIII for 0.015-in. feed is high at 1.93. This latter value was practically thrown out from the consideration. The values for cast iron are also very close for the different feeds and bars which indicates that 1.98, or an even 2, would serve well as an average value as an exponent for the drill diameter. The torque then for any material at any feed and speed may be expressed as: $T = C f^{0.8} d^2$, for cast iron, and $T = C f^{0.78} d^{1.8}$, for steel in which T is the torque in foot-pounds, d is the drill diameter in inches, f is the feed in inches, C is the function of the material to be determined by some means not now known to the author, unless some actual cutting tests have been performed on the particular material, from which C can be found. The nature of this constant is similar to the "hardness class" used by Taylor[12] and Barth, and it is the factor which determines the location of the materials in Fig. 5 or Table 11. Knowing the torque for a given drill diameter, feed, and speed in a certain metal, the torque at the same feed and speed (or any other speed) but for a different drill diameter may be determined as follows: $\frac{T_1}{T_2} = \frac{d_1^n}{d_2^n}$, in which T_1 and d_1 are the known torque and drill diameter and T_2 is the desired torque for the new diameter d_2; n is 2.0 for cast iron and 1.8 for steel.

The values of the thrust for steel bar IIIIII and cast-iron

[1] C. 0.33, Mo. 0.18, Cr. 0.66 (see Table 1).
[2] C. 0.28, Mo. 0.19, Cr. 0.65 (see Table 1).

bar 8 A at the three different feeds of 0.015, 0.012, and 0.009 in., the torque values for which were reported in Fig. 20, were also plotted on the log-log paper. The following values for n were obtained:

Bar IIIIII at a feed of 0.015 in..... $n = 1.1$
Bar IIIIII at a feed of 0.012 in..... $n = 0.955$
Bar IIIIII at a feed of 0.009 in..... $n = 1.09$
Bar 8-A cast iron at a feed of 0.012 in..... $n = 1.04$

Also the thrust values for steel bar 6 and cast-iron bar 20 as

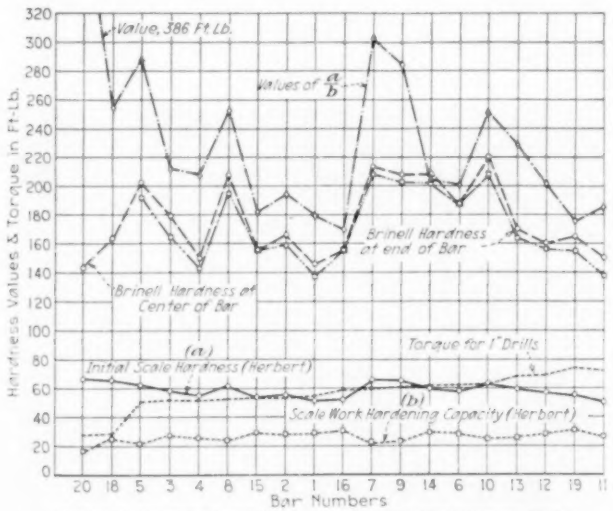

FIG. 23 CORRELATION OF DRILL TORQUE, BRINELL, AND HERBERT SCALE HARDNESS

reported in Fig. 22, were plotted on log-log paper, and the value of n was found to be as follows:

Bar 6 (S.A.E. 6150) at a feed of 0.015 in..... $n = 1$
Cast-iron bar 20 (4–8–28) at a feed of 0.015 in..... $n = 1$

It is concluded from the above values that the thrust varies almost exactly in direct proportion to the diameter of the drill. The values for thrust may be expressed then, as follows:

$$Th = C f^{0.8} d, \text{ for cast iron, and}$$
$$Th = C f^{0.8} d, \text{ for steel.}$$

The constant or "hardness class" C, will vary with the individual metal tested.

VARIABLE DIAMETER TESTS—RESULTS OF OTHER EXPERIMENTERS

H. M. Norris[13] concludes that when the speeds and feeds remain constant the power required is approximately proportional to the diameter of the drill.

Smith and Poliakoff[14] conclude that the torque increases almost in proportion to the square of the diameter of the drill for a given feed. The thrust is assumed to be a linear function. Their curves, however, show that the thrust curves for various feeds for a particular diameter do not pass through the origin, so that the conclusion is obviously wrong. They further conclude that the net horsepower for a given feed and speed does not increase as fast as the diameter, but varies as $d^{0.5}$. They further conclude that the net horsepower when operating on soft

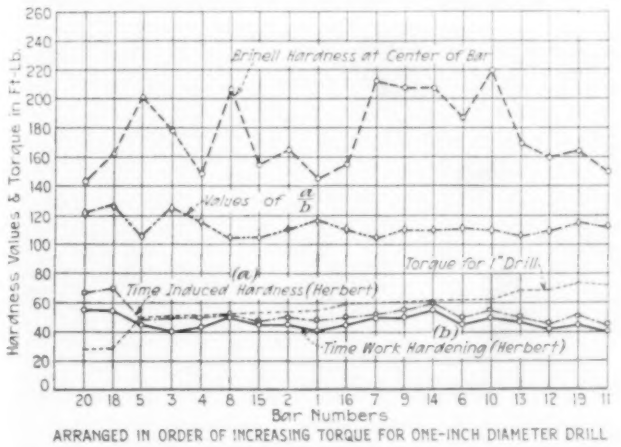

FIG. 24 CORRELATION OF DRILL TORQUE, BRINELL, AND HERBERT TIME HARDNESS

cast iron or medium steel varies as $t^{0.7}$ (feed), for a given drill and speed.

CORRELATION OF THE PHYSICAL PROPERTIES OF MATERIALS CUT WITH THE DRILL TORQUE

The values of the torque for the commercial speeds and feeds given in Table 5 for each drill diameter are plotted over the material numbers arranged in order of increasing torque on the 1-in. drill for its commercial cutting condition of 228 r.p.m. (60 ft. per min.), and a feed of 0.013 in. per revolution. These torque curves are satisfactorily smooth. A satisfactory mathematical equation might be written to represent the torque for a given drill and cutting condition, if some factor representing the machinability of the metals were known. In order to show part of the investigation on the correlation of physical properties with the drill torque, Figs. 23 and 24 were prepared.

In Fig. 23, the torque in foot-pounds for the 1-in. diameter drill, rotating at 228 r.p.m., and at a feed of 0.013 in. per revolution is shown plotted in light dashed lines over the bar numbers as abscissas arranged from left to right in order of increasing torque. The torque values for the two cast-iron bars 20 and 18 are about 27.7 and 27.9 foot-pounds respectively. The torque of 50.8 foot-pounds for steel bar 5, is the lowest of all the steels, while a torque of 74 foot-pounds for bar 19 is the highest. To the same scale as ordinates are also plotted in this figure the Brinell hardness numbers as taken at the end of the bar, at the beginning of the experiments, and at the center of the bar, for check purposes at the conclusion of the experiments, after

milling off approximately 1/4 in. of metal. While these Brinell curves are practically parallel and equal, they show a wide divergence in curvature from the torque curve. The initial scale-hardness values determined by the Herbert pendulum hardness tester is also given in the form of a curve in this figure, together with the scale work-hardening capacity. Neither of these curves appear to explain the reason for the constantly increasing drill torque, from left to right. In order that the scale "work-hardening capacity" might be tied up with the initial scale "hardness," another curve, representing the initial scale "hardness" divided by the scale "work-hardening capacity," is shown. This latter curve shows a general tendency to slope downward to the right, while the drill-torque curve slopes upward. The scale-hardness values, however, appear not to be connected with the drill-torque, although they do follow closely, the Brinell numbers.

Fig. 24 shows over the bar numbers arranged as abscissas, in order of increasing torque for the 1-in. diameter drill, curves for the drill-torque for the 1-in. drill, the Brinell hardness numbers at the center of the bar, and three time-hardness curves, such as the time-work-hardening curve, the time-induced-hardness curve, and a curve representing the ratio of the time-induced-hardness to the time-work-hardness values, as determined by the Herbert pendulum hardness tester. Again, there appears to be no definite relation between these time-hardness curves and the torque curve. The author's experience with the Herbert pendulum hardness tester is limited to the tests presented here. The values for each bar are an average of at least two test values which were equal or nearly so. The instrument was repeatedly checked at intervals on plate glass throughout the tests.

In the hope of throwing additional light on the relation of the metals drilled to their drill-torque value, a metallographic study of the various samples was made. Photomicrographs for the metals are shown in the order of increasing torque for the 1-in. drill in Figs. 25 to 55, inclusive. Photomicrographs at 100 diameters are presented for all samples in the etched condition; a 4 per cent Nital solution was used. Photomicrographs at 1000 diameters are also presented for a number of the samples to bring out differences in structure not evident at the lower magnification, particularly the difference in the character of the pearlitic structure. Some of the samples show little tendency for spheroidization, while others show practically complete spheroidization.

The results of the metallographic study may be summed up, as follows: Based on microstructure the 17 samples of steel may be somewhat arbitrarily divided into three classes. In the first class are placed those steels which show a normal pearlitic structure, or one showing very slight spheroidization; in the second class are placed those steels which are partly spheroidized, that is, advanced beyond the beginning stage of spheroidization; and in the third class, are placed those steels which are completely, or very nearly completely, spheroidized. Those steels falling in class one, are bars 5, 3, 1, 4, 8, 15, and 2, in class two are bars 16, 7, 9, 6, and 10, and in class three, bars 13, 12, 19, 11, and 14. In Fig. 10 or 11, it is seen that the torque curve is practically horizontal for the first group, consisting of bars 5 to 1, inclusive, and higher but practically horizontal for the second group of 16 to 10 inclusive, and again, higher but practically constant for the third class of 13 to 11 inclusive. It should be noted, however, that bar 14 in Fig. 23 is out of order, as it appears with class two rather than with the metallographical class three. Bar 6 is also, in a way, an exception to the second metallographic class, in that it appears to be more of the sorbitic type of structure than that of the partially spheroidized pearlitic.

In, pointing out the above relationship it is not intended to attempt to justify the drawing of any general conclusions connecting machinability with structural characteristics. There are many other factors which enter into a correlation between drill torque (machinability) and the structure. The wide variation in the chemical composition of the specimens used necessarily makes impossible the drawing of any general conclusions. The results of this investigation indicate, however, that for the particular type of tests made and the materials used, a classification from a structural standpoint exists, with the exception of bar 10. This appears to be a classification from a horizontal standpoint, that is, the bars are grouped into three groups along the abscissa axis according to the degree of spheroidization. A direct connection with the torque curve of Fig. 23 is evident, although the greater the torque the greater is the degree of spheroidization. This is just the opposite of what might be expected if all bars were of the same chemical composition.

Considering the specimens from the standpoint of composition some interesting relationships appear. Table 11 shows the materials grouped according to chemical composition in order of increasing torque on the 1-in. drill as shown in Fig. 23.

It will be observed that arranging the specimens in order of increasing torque, a fairly close grouping according to chemical composition or type of steel is obtained. Two steels fail to conform to this grouping. These two exceptions are bar 19 of tool steel, and 10 of nickel steel, S.A.E. 2340. The grouping, however, is not consistent from the standpoint of increasing or decreasing carbon content. With some of the types of steel an increase in carbon content is accompanied by an increase in torque, with other types the reverse is true.

The carbon steels ranging from 0.20 to 0.95 carbon show a rather wide divergence in torque. Five other steels show lower torque than the 0.45 and 0.20 carbon steels which are found together, while only one, the 6120, shows as high a torque as the 0.95 carbon. The 0.45 carbon steel which shows a lower torque than the 0.20 carbon steel shows a banded structure with pearlitic slightly spheroidized as opposed to 0.20 carbon steel in which little or no banding appears, and in which the pearlitic shows no indication of spheroidization. The 0.95 carbon steel is, however, fully spheroidized.

The chrome-nickel steels which have been divided according to nickel content show the torque to increase with increasing nickel content. As with the carbon steels, the grouping does not appear consistent from the standpoint of carbon content. The differences in microstructure are not such as to explain the apparent reversal in order.

The nickel steels show a very wide divergence in torque for a correspondingly small difference in carbon content. A similar variation in carbon content for the 1 per cent and the 2 per cent nickel-chrome steels results in no appreciable change in torque. Here the difference in torque appears to be clearly related to microstructure. The nickel-chrome steels which are found together on the basis of torque have similar microstructures; the two nickel steels which are widely separated on the basis of torque have very different microstructures. Bar No. 3, the 2320 steel, shows a distinctly banded structure, coarse grained, and with pearlitic showing very little spheroidization. Bar No. 10, the 2340, shows a very slight banding, fine grained, and very largely spheroidized.

The chrome-molybdenum steels behave similarly to 0.20 and 0.45 carbon steels, the higher carbon showing slightly lower torque. The lower carbon molybdenum steel, however, shows a greater spheroidization of the pearlitic.

The chrome-vanadium group of steels are consistent with the 2 per cent nickel-chrome steels, and the chrome-molybdenum

steels in that increasing torque accompanies decreasing carbon content. Of these steels, three are practically 100 per cent spheroidized. The other, Bar No. 6, S.A.E. 6150, appears to be more of a sorbitic structure. The torque values for the three bars Nos. 13, 12, and 11, all of which had the same heat treatment, seem to indicate quite definitely, at least for this type of steel, that increasing carbon content decreases the torque when the steel is fully spheroidized. The silico-manganese steel which was fully spheroidized falls in the class showing higher torque value.

Table 11 would appear to indicate that the type of steel, the carbon content, and the microstructure are all very important factors in determining torque.

With reference to the photomicrograph showing the two cast irons, it will be evident that structural differences are not what would normally be expected from a commercial cast iron, and an iron made with addition of charcoal pig. In fact, the structures appear to be reversed, although neither one gives the characteristic appearance of an iron made with the addition of charcoal pig.

Conclusions

In arriving at the conclusions given it is to be understood that the drills used were supposed at all times to have a keen cutting edge and point, that is, they were in a sharp condition. A cutting fluid consisting of one part of soluble oil mixed with sixteen parts of water was used on all tests. Actual experimental results are given in every instance, rather than values determined by smoothing out curves. For this reason there will be some slight inconsistencies in the data presented.

1 The torque remains practically constant at speeds ranging from 74 to 441 r.p.m. for both cast iron and steel and for various drill diameters when operating under constant conditions of feed, lubrication, and material.

2 The thrust remains practically constant at speeds ranging from 74 to 441 r.p.m. for both cast iron and steel and for various drill diameters when operating under constant conditions of feed, lubrication, and material.

3 The net input which equals the gross minus the load on the machine running idly, increases directly with the speed for the conditions mentioned under 1 and 2.

4 The torque increases with the feed, but at a slower rate for a constant drill diameter and speed. For two cast irons, one carbon, and one alloy steel for various drill diameters from $^1/_2$ to $1^1/_2$ in. and for different speeds, the average conditions are represented by the following:

T = a function of $f^{0.6}$, for cast iron, and
T = a function of $f^{0.78}$, for steel.

5 The thrust increases with the feed, but at a slower rate when drilling cast iron and steel. For the conditions mentioned in 4, the following formulas represent average values:

Th = a function of $f^{0.6}$, for cast iron
Th = a function of $f^{0.6}$, for a carbon and an alloy steel.

6 In drilling a straight-carbon and an alloy steel with drills varying from $^1/_2$ to $1^1/_2$ in. in diameter, at constant speeds of 153 and 230 r.p.m., the torque increases with the drill diameter, but at a greater rate for both cast iron and steel. Average conditions for two cast irons, a plain carbon, and an alloy steel are represented as follows:

T = a function of d^2, for cast iron
T = a function of $d^{1.8}$, for steel.

This may be expressed again, as follows:

$\frac{T_1}{T_2} = \frac{d_1^n}{d_2^n}$, in which T_1 and d_1 are the known torque and drill diameter and T_2 is the desired torque for the new diameter d_2. n is 2.0 for cast iron and 1.8 for steel.

7 For the conditions outlined under 6 the thrust is found to vary almost exactly in direct proportion to the diameter of the drill. The values for thrust may be expressed then, as follows:

Th = a function of d, for cast iron, and
Th = a function of d, for steel.

8 Combining the above relations of torque and thrust for cast iron and steel, general equations may be written as follows:

$T = C_1 f^{0.6} d^2$, for cast iron,
$Th = C_3 f^{0.6} d$, for cast iron,
$T = C_2 f^{0.78} d^{1.8}$, for steel, and
$Th = C_4 f^{0.6} d$, for steel, in which T is the torque in foot-pounds, Th is the thrust in pounds, d is the diameter of the drill in inches, f is the feed of the drill in inches per revolution, and C may be called a "hardness class" number, or "machinability factor," that is, a constant depending upon the material being drilled. At the present time the authors know of no way, except by actual drilling tests, to predetermine these constants for torque and thrust, for a particular metal.

9 The output horsepower at the drill point may be computed from the torque T and thrust Th, from the formula

$$\text{Hp. (computed output)} = \frac{2\pi TN}{33{,}000} + \frac{ThfN}{12 \times 33{,}000} = 0.0001904\ TN + 0.00000252\ ThfN = N\ (C_5 T + C_6\ Th\ f),$$

in which N is the r.p.m. of the drill, f is the feed in inches per revolution of the drill and C_5 and C_6 are constants. It is seen then that the output horsepower at the drill point as computed from the torque and thrust is directly proportional to N. While the value of the thrust in pounds is usually relatively large, the resultant horsepower is only $^1/_2$ to 2 per cent of the total computed. For general purposes, then, the output horsepower developed at the point of the drill may be assumed to be due only to the torque or

Hp. (computed output) = $0.0001904\ TN$ in which
$T = C_1 f^{0.6} d^2$, for cast iron, or
$T = C_2 f^{0.78} d^{1.8}$ for steel.

10 The results of the metallographic study may be summed up as follows: The seventeen samples of steel as a group are arbitrarily divided into three classes, the first class showing a normal pearlitic structure, or one showing a very slight spheroidization; the second class consisting of those steels which are partly spheroidized, that is, advanced beyond the beginning stage of spheroidization; and the third class, those very nearly completely spheroidized. A direct connection with the torque in drilling as shown in Fig. 23 is evident, although the greater the torque the greater is the degree of spheroidization. This is just the opposite of what might be expected if all bars were of the same chemical composition.

11 By grouping the materials according to chemical composition in order of increasing torque on the 1-in. drill as shown in Fig. 23, a fairly close grouping according to chemical composition, or type of steel, is obtained. This arrangement tends to indicate that the type of steel, the carbon content, and the microstructure are all important factors in determining the value of the torque in drilling.

12 No satisfactory correlation between the hardness values as determined by the Brinell, Rockwell, scleroscope, or the Herbert pendulum hardness tester, and the drilling torque for a given specimen, is evident.

Acknowledgments

The authors wish to express their appreciation to the Uni-

versity of Michigan whose equipment and laboratory space was used for these tests, also to those who have assisted in the investigation and preparation of the data as follows: George Butters, Giles Barr, Raymond Johnson, and others, who assisted in conducting the tests and tabulating the data; to Warner Vaughan who assisted in the various computations and in drawing the curves; to Professor Claire Upthegrove of the Department of Chemical Engineering who prepared the photomicrographic discussion, and to William Telfer who assisted in the hardness determinations of the various specimens.

Acknowledgment is also made to the Engineering Laboratory of the Ford Motor Company which furnished the Herbert pendulum tester for the determination of the scale and time-hardness values of the metals.

MSP-52-3

The Present Status of Cemented Tungsten Carbide Tools and Dies

By ZAY JEFFRIES,[1] CLEVELAND, OHIO

I HAVE accepted the invitation to lead the discussion this evening as a representative of what might be called the cemented tungsten carbide industry in America. I am associated with one of the companies manufacturing and selling cemented tungsten carbide in America, namely, the Carboloy Company, Incorporated. There are, however, three other main channels of manufacture and distribution in the United States. These are Thomas Prosser & Son, who are representatives of Fried. Krupp, and they deal largely with imported cemented tungsten carbide material made by the Krupp company in Germany. Also the Firth-Sterling Steel Company manufactures and sells under the trade name "Diamondite" a similar material, and the Ludlum Steel Company deals in a similar material known as Straus Metal.

Before preparing the discussion this evening I communicated with the other representatives of the cemented tungsten carbide industry and obtained information from them as to their opinion of the present status of this industry in America, so that in a sense I have come before you to present a sort of composite picture for the whole industry. I shall make no distinction, nor do I intend to imply that there is any fundamental difference between one brand of cemented tungsten carbide and another. The examples of performance to be reported later represent all of the brands.

Cemented Tungsten Carbide—Its Origin

The base metal of cemented tungsten carbide is tungsten. The hard component is tungsten carbide. It was known at least toward the middle or last third of the last century that ferrotungsten containing large percentages of carbon was excessively hard. The material, however, was also very brittle. Moissan, about 1898, produced in the electric furnace from tungsten oxide and carbon, a material which he described as a carbide of tungsten and he reported that it was very hard. There were no common methods for determining hardness in those days except the scratch method, but the hardness was sufficient to attract Moissan's attention.

About 1904 Just and Hanamann in Budapest invented the squirted, or pressed, tungsten lamp filament. In the process of making the filament they produced, in one stage, tungsten containing a small amount of carbon. Such filaments were so brittle and fragile that it seemed doubtful whether they would be commercial. In fact, as little as one-tenth to twenty-five hundredths of one per cent carbon in such filaments rendered them not only brittle, hot and cold, but rendered them so fragile that a large percentage were broken merely by handling. The tungsten lamp-filament industry, therefore, has been engaged in a battle against carbon from about 1904 until the present time. Even now, at times, carbonaceous material gets into the lamp and a little tungsten carbide forms at the grain boundaries of the tungsten near the point where the filament is joined to the leading-in wire. Under such conditions the tungsten becomes so brittle and fragile that a slight jar of the lamp breaks the filament.

Also, in one of the processes of treating tungsten wire, the filament is heated to a temperature around 1200 deg. cent., usually in an atmosphere of hydrogen. It was early learned that if the atmosphere were changed to a hydrocarbon atmosphere, say, by introducing a little kerosene or alcohol or gas, within a few seconds the filament became so brittle and fragile that it could be broken to pieces in the fingers. This resulted, notwithstanding the fact that the filament before the treatment had a tensile strength of 600,000 lb. per sq. in., and was quite ductile. The percentage of carbon required to produce this bad effect in tungsten was so small at times that it was difficult to detect it by chemical analysis.

It seems rather remarkable because of the fragility of tungsten containing a little carbon or fused tungsten carbide that the material which we are to discuss this evening could contain to from 85 to 95 per cent of tungsten carbide and be sufficiently tough for cutting-tool purposes.

Method of Producing Cemented Tungsten Carbide

The creation of this material represents a new metallurgy. The old metallurgy, especially the tool metallurgy, was essentially one of fusion and either use of the tool in the cast condition, with or without heat treatment, or the use of the tool after forging plus heat treatment. The present cemented tungsten carbide is produced by first manufacturing a very fine powder of tungsten carbide. The fine powder is then mixed with metallic cobalt. The mixture is then ball-milled, and, as Dr. Hoyt has shown, the action causes the cobalt to be smeared over the surface of the minute microscopic particles of the carbide. The mixture, after ball-milling, is then pressed into any desired shape and size. It may be partially sintered then by heating to a low temperature, in which condition it can be handled without breaking, and can be easily shaped with a steel tool. It is not really machinable in the sense that the metal can be cut by an ordinary tool, but partially sintered powder can be removed with ease.

The final sintering is done in an electric furnace with a hydrogen atmosphere at a brilliant white heat. This is the true cementing operation, and cobalt is the cementing material. It is known that the cobalt takes up a little of the tungsten carbide in the process, but essentially the finished product consists of minute particles of tungsten carbide cemented together with cobalt, or with cobalt containing some tungsten and carbon.

This material was developed in Germany by the Osram Lamp Works, Berlin, and the two men who are given the major credit for the development are Schroter and Baumhauer.

The development was first made for wire-drawing dies. The dies were to be used for drawing tungsten and molybdenum at elevated temperatures. Dr. Hoyt, of the Research Laboratory of the General Electric Company in Schenectady, started development work several years ago along the lines originally suggested by Schroter and Baumhauer. He made additional contributions to the development, and others have contributed also. The cemented tungsten carbide of today therefore represents the work of a good many people, not only in Germany but in this country as well.

Properties of Cemented Tungsten Carbides

In density, cemented tungsten carbide ranges, say, between

[1] Metallurgical Engineer and Consultant, Incandescent Lamp Department, General Electric Co., Nela Park.

Address delivered at a meeting of the A.S.M.E. Machine Shop Practice Division, Cleveland, Ohio, October 1, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

14 and 15, sometimes lower, sometimes a little higher, so that it is relatively dense. Its hardness is difficult to appraise. It has a very high resistance to abrasion. Its resistance to indentation is relatively less than one might expect from its resistance to abrasion. The tungsten carbide itself has a hardness about com-

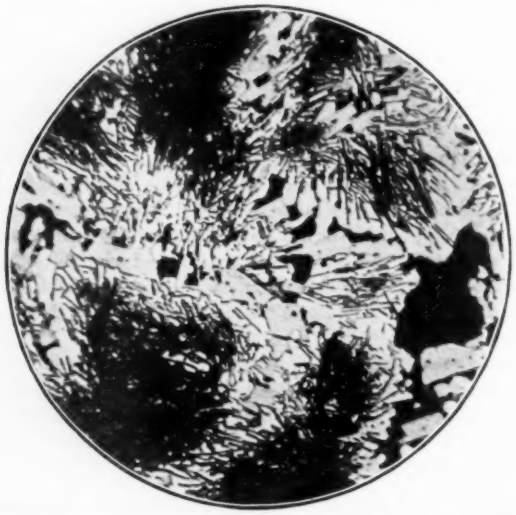

FIG. 1 PHOTOMICROGRAPH OF SECTION OF FUSED TUNGSTEN CARBIDES × 1000 (HOYT)

(Very hard but very brittle and quite fragile. Known for many years and unusable.)

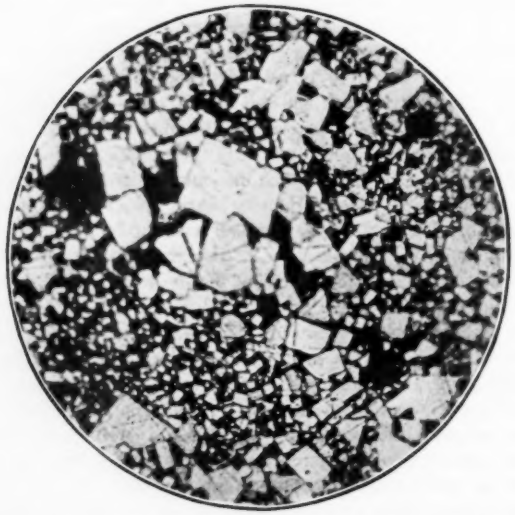

FIG. 2 ONE OF THE EARLIER CEMENTED TUNGSTEN CARBIDES × 1000 (HOYT)

[Showing carbide particles (light) surrounded by cobalt cement (dark).]

parable to sapphire or to corundum. The scratch hardness of the cemented tungsten carbide is equal to the hardness of the hardest constituent, hence is equal to the hardness of the tungsten carbide. The indentation is made easier by the presence of the cobalt, and hence the indentation hardness is relatively low as compared with the scratch hardness and as compared with the wear resistance of the material. The ordinary Rockwell hardness measurement on the C-scale will not suffice generally for the hardness measurement, but a smaller load is used, and a special hardness scale (the A-scale) is used for these materials. Other devices, such as the Vickers machine and the Monatron, as well as the Rockwell, can be used to evaluate the indentation hardness. There is no test for wear resistance equal to the service of tools in use, so that the appraisal of that factor is pretty much left to the user.

Whereas high-speed steel requires a special heat treatment to develop its hardness, cemented tungsten carbide is fully hard after cooling to room temperature from the high-temperature sintering operation. It cannot be softened by heat treatment alone. It can be reheated to a very high temperature and cooled either rapidly or slowly and it is still hard. Its red-hardness surpasses that of any other metallic substance used in the tool industry. No one knows just how hard it is at the high temperature, nor at what rate its hardness decreases at the higher temperatures. At any rate it appears that temperatures which are ordinarily reached even in relatively severe industrial operations are not high enough to materially affect the red-hardness of cemented tungsten carbide.

There are several ways of making cemented tungsten carbide, and there are two or three different grades available to the trade. These grades differ both in composition and in treatment during preparation. They differ in physical properties as well. One of the grades contains about 87 per cent of tungsten carbide and

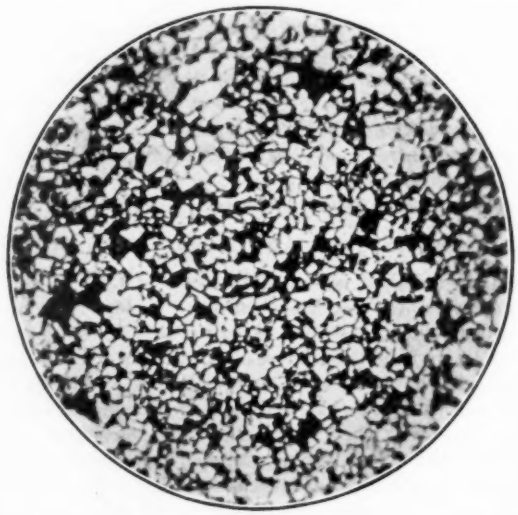

FIG. 3 ONE OF THE NEWER CEMENTED TUNGSTEN CARBIDES × 1000 (HOYT)

(Note that grain is finer and more uniform than in Fig. 2.)

13 per cent of cobalt. This grade is tough, having at times a calculated tensile strength, as determined by the transverse test, of 300,000 lb. per sq. in. It has a high compressive strength, one determination being 540,000 lb. per sq. in., the highest of any material which has been tested in our laboratory. Another grade contains about 6 per cent of cobalt. It is somewhat harder as measured by the indentation test and considerably harder as measured by the abrasion or wear test, and not so strong as measured by the transverse breaking test.

The industry is so new that the multiplication of grades has not reached the public. It is possible, however, by slight changes in composition and in methods of manufacture to produce quite a range of properties, and it seems practically certain that as time goes on industry itself will select from these possibilities what best suits its own purposes. Like every other new industry it has not begun to exhaust the possibilities of the present grades, but the time will come when additional grades will be available. We are hardly at the stage where we can measure small differences so that it is not surprising that relatively few grades would meet most of the requirements at hand. Also, those exploiting ce-

mented tungsten carbide are so busy with the grades they have that they lack the energy to consider additional grades at the present time.

Cost

Cemented tungsten carbide is offered to the trade at a relatively high price—in round numbers, $450 per pound. That, of course, is more than the material will cost in the future, and it is a price which none of us expect will be maintained in the industry. On the other hand, the industry is in the process of development, and development costs a great deal of money.

The first people to make investment in cemented tungsten carbide were those who carried on investigations and researches leading to its invention. The next group comprised the companies commercially exploiting the material. Following these came the machine-tool builders.

Having visited the National Machine Tool Builders' Exposition I can appreciate that the machine-tool builders have already put some hundreds of thousands of dollars into the development of machines which will have sufficient power for and be otherwise adapted to the use of cemented tungsten carbide, but before they did that, other groups put a considerable amount of money into researches on the nature of the material itself, on how to make it, and on how to use it. I cannot speak for the other groups, but the Carboloy Company is still spending money faster than it receives it.

In spite of the present price, in most of the analyses which we have we find that the user of the material employs it at a distinct saving to himself, so if any one should complain about the price it should not be he who buys a tool and uses it at a profit to himself, but those who are exploiting the material and the machine tool builders, both of whom have investments on which they have so far not realized any profit.

Utilization of Cemented Tungsten Carbide in Tools

Being a high-priced material, cemented tungsten carbide is utilized by the insertion of a tip in a shank of a cheaper material, usually some grade of steel. This has given rise to what is known as the tipping problem. Tipping has been taken care of in a number of ways. The art of tipping may not be all that is desired at the present time, and improvements can be expected in the future, but it has been found possible to put the cemented tungsten carbide tips on steel shanks by copper brazing in an atmosphere of hydrogen, with satisfactory results in most cases. There seems to be a preference for the welded tip for larger tools. The welding is attended by the hazard of cracking the cemented tungsten carbide itself, but when properly manipulated this hazard can be overcome. Both the welded tips and the brazed tips have been found satisfactory in service.

Not a sufficient number of people throughout the industry are conversant with the art of tipping to distribute cemented tungsten carbide to the industry haphazardly. On the other hand, some of the industrial companies have worked on this problem and are in a position to make their own tools. If a concern has only a little tipping to do, it is probably best to permit one of the companies specializing in putting on these tips to make the tools. All of the companies exploiting this material in America have organizations for doing the work, and these of course are at industry's service. At the present time, therefore, there are two ways of acquiring a tool: one is to design the tool and order it

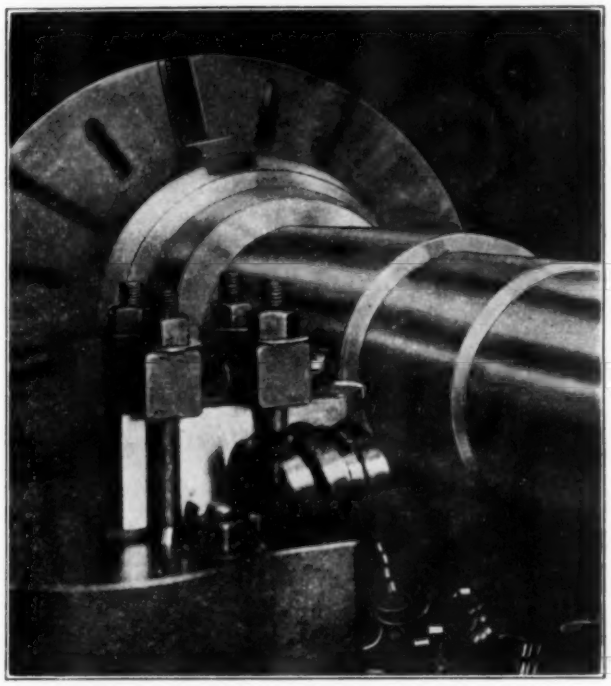

Fig. 4 Turning a Chrome-Nickel Steel Test Log With a Cemented Tungsten Carbide Tool

(Speed cutting, 70–75 ft. per min.; feed, 0.044 in.; cut, 3/8 in. A high-speed-steel tool lasts about 16 sec. on this test; cemented tungsten carbide is required to last 10 min., and may run for several hours.)

Fig. 5 Use of Cemented Tungsten Carbide Tools for Large Operations—Planing Section of Steel Flywheel, or Boring Mill, With Two Tools

tipped and ground, and the other is to buy the material and make the tools yourselves. There may be some advantage to the exploiters of this material in the latter method because companies

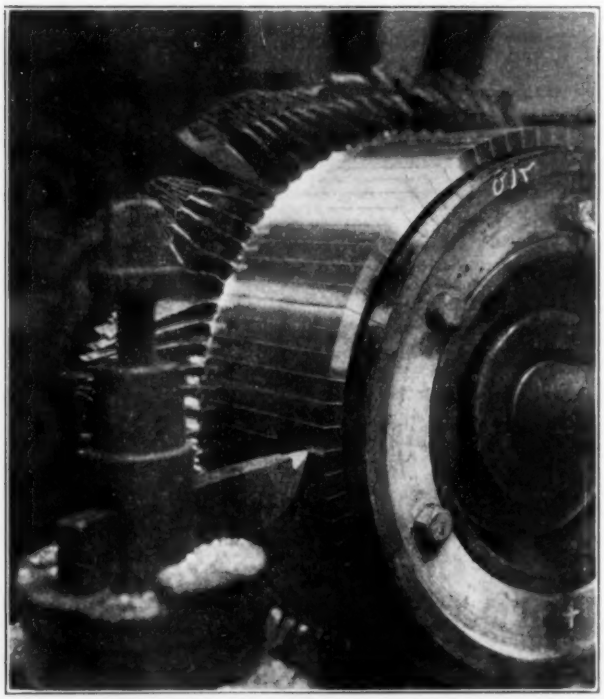

FIG. 6 TURNING A COMMUTATOR WITH A CEMENTED TUNGSTEN CARBIDE TOOL

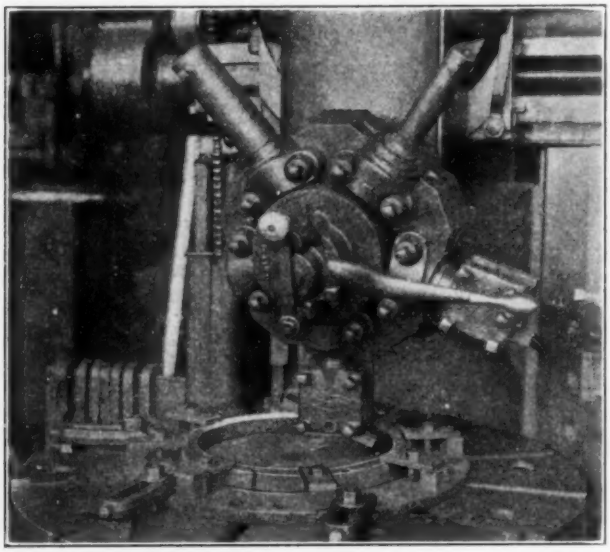

FIG. 7 TURNING A CARBON PACKING RING WITH A CEMENTED TUNGSTEN CARBIDE TOOL

putting on their own tips are satisfied with very much poorer jobs of tipping than when buying finished tools. If the cemented tungsten carbide cracks during the tipping or grinding operation in one's own plant he uses the tool anyway, and finds sometimes that it lasts as long as if the crack were not there; but if he orders a finished tool he rightfully demands that it shall be free from defects.

TOOL GRINDING

The next problem in connection with the manufacture of a tool is grinding, and without attempting to go into detail it may be said that there are several companies in the United States that sell wheels suitable for the grinding of these materials. The base material for these grinding wheels is in most cases, and perhaps

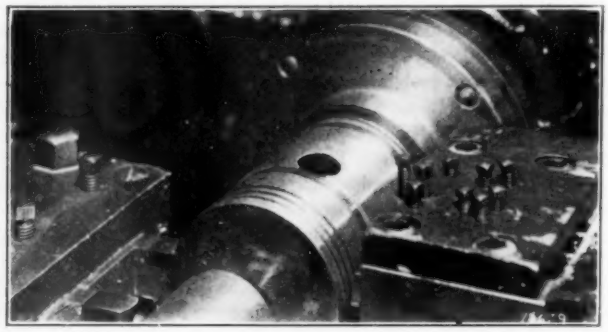

FIG. 8 MACHINING AN ALUMINUM-ALLOY AUTOMOBILE-ENGINE PISTON

(Metal is a high-silicon alloy, machinable only with the greatest difficulty with ordinary tools; about 10 pistons before dulling; with cemented tungsten carbide tools some of the operations will run 300 to 500 pistons between grinds, and with others, 2500.)

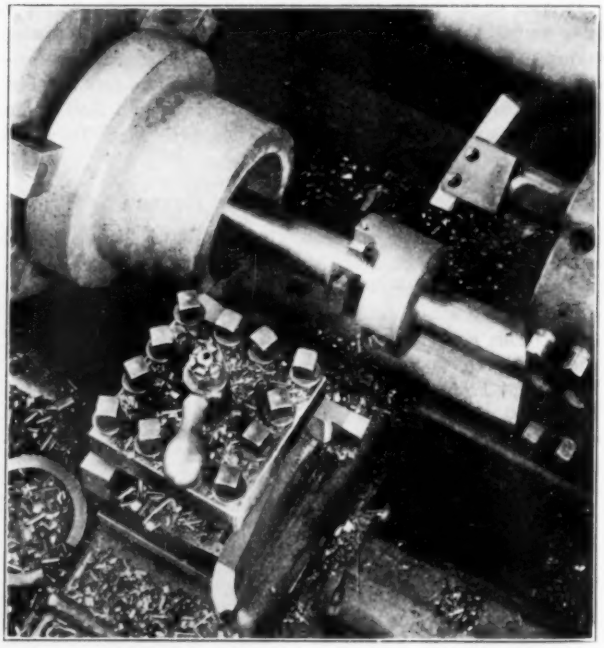

FIG. 9 ROUGH BORING AND FACING WITH CEMENTED TUNGSTEN CARBIDE TOOLS

all cases, silicon carbide, known as carborundum, or crystolon. Whereas six or eight months ago the matter of grinding these tools was a serious one, at the present time it may be said that that problem has at least passed the temporary crisis. There are certain precautions which the user will soon learn, but the information can be obtained from any of the companies exploiting this material and from the grinding-wheel companies.

USES OF CEMENTED TUNGSTEN CARBIDE

Now as to the uses of cemented tungsten carbide. The branch of the Society represented here tonight is principally interested in

machine-shop practice, or the use of tools in machining. The material—cemented tungsten carbide—has a much broader application. I shall mention a few cases to show some of the applications of this material, and so far as I know each case cited is a commercial one and not an exceptional performance.

There seems to be a tremendous field for its use in wire-drawing dies. I shall give two examples, one in which the competing material is the diamond die and the other is the chilled-iron die. In the first case the cemented tungsten carbide die drew 57,800,000 ft. of screen wire, 0.0108 in. in diameter, with a wear of 0.0007 in. in diameter. At this size the performance was approximately equivalent to that of a diamond die, but with more cuts possible in the case of cemented tungsten carbide. The overall improvement in cost on a performance basis over diamond was 6 to 1. The second example is the drawing of steel wire 0.105 in. in diameter. Over a 12-day period 264 chilled-iron dies were used in this line. Over the same period one cemented tungsten carbide die performed without going off size, or one cemented tungsten carbide die took the place of 264 chilled-iron dies. On the basis of die cost alone the cemented tungsten carbide was cheaper than the chilled iron in the ratio of 36.6 to 18. In addition, 20 per cent more wire was produced during the period

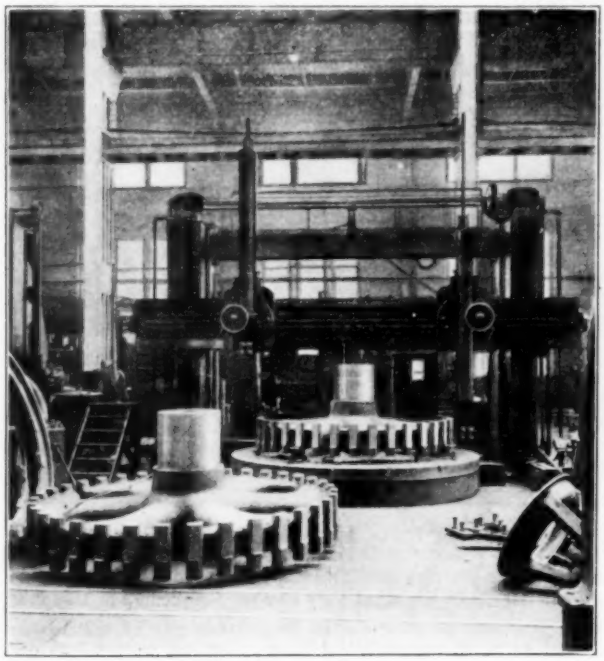

FIG. 10 COMMERCIAL USE OF CEMENTED TUNGSTEN CARBIDE TOOLS ON INTERMITTENT CUTS—TURNING LARGE CAST-IRON ROTOR SPIDER

by the one cemented tungsten carbide die than by the 264 chilled-iron dies. Cemented tungsten carbide dies are also being used for the hot drawing of tungsten and molybdenum, and more will perhaps be heard in the future about its use in the hot drawing of other materials.

The material is also usable in blanking dies, and in particular by the General Electric Company in punching transformer disks. It is found that the cemented tungsten carbide blanking die produces a material free from burrs. In blanking 200,000 disks the first one and the last appeared to be just alike.

ABILITY TO CUT HITHERTO UNMACHINABLE MATERIALS

Cemented tungsten carbide is used for cutting materials which no other metallic material has been able to cut. In that sense it is opening up a new field for machining. Machining is only one method of shaping articles, and has been used to a much greater extent in shaping metals than it has for everything else combined.

Cemented tungsten carbide can machine glass, porcelain, compounds used in the electrical industry such as Micalex, ivory, and materials of that sort. It machines various non-metallic

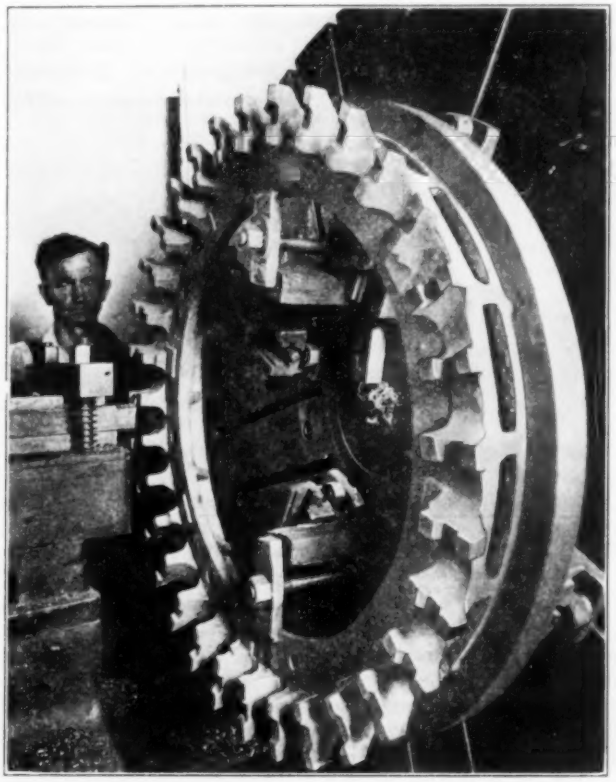

FIG. 11 ANOTHER EXAMPLE OF USE OF CEMENTED TUNGSTEN CARBIDE TOOLS ON INTERMITTENT CUTS

materials known as the fibrous materials which are abrasive, those containing mixtures of asbestos and other materials used in brake linings and floor boards, and it machines molded products of the bakelite type. In some instances it replaces diamond in those operations, but in other instances it makes possible the machining of parts which heretofore could not be shaped economically by machines with any known tool. Just where that will lead in the future, no one knows, but I think it should be a very interesting possibility as viewed from the standpoint of the Machine Shop Practice Division of The American Society of Mechanical Engineers.

The material is also used for cutting rock. It can be used to saw rock, replacing the old-time sawteeth of other materials with cemented tungsten carbide. It is also used in gages, knife edges, blast nozzles, etc.

It should be obvious that when a new tool material with the capabilities of cemented tungsten carbide is made available, existing machines may not be able to take full advantage of it. Nevertheless, the machines which have been made during the past five, ten, or even fifteen years have been adapted, in a way, to use this material, and whereas one would not expect a maximum performance from these machines, it is interesting to see what performance has been obtained.

Comparative Examples of Tool Replacement

In turning a laminated armature by the old tooling methods and tools the performance was one armature per grind. With cemented tungsten carbide 40 armatures were turned per grind. The speed was 700 ft. per min., hand feed, and the cut $^1/_{64}$ in.

For rough and finish turning commutators, the old record with the existing tools was 150 pieces per grind; with cemented tungsten carbide it was 30,000 pieces per grind.

Another example is a cut-off tool; the old performance was 100 cuts per grind; cemented tungsten carbide, however, made 15,000 cuts per grind.

In profiling 1020 S.A.E. steel at very high speed the old practice was 60 pieces between grinds; with cemented tungsten carbide it was 25,000 pieces.

Fig. 12 Heavy L-Shaped Tool for Intermittent Cuts
Tool, $1^1/_4$ in. deep; shank, 1 in. wide; L, $1^3/_4$ in. wide; inserted cemented tungsten carbide tip, $^3/_4$ in. × $1^1/_4$ in. × $^7/_{16}$ in. thick.)

Ivory has been turned at 6000 ft. per min., hand feed, with only a skin cut, with a result about the same as that obtained with a diamond tool.

In boring main-transmission-bearing holes $4^1/_2$ in. in diameter, in cast iron, 100 to 125 pieces per grind with the old tools was considered good, but 950 per grind were machined with cemented tungsten carbide.

In finishing boring of a bronze bushing with a tolerance of 0.0005 in., the old record with existing tools was 150 per grind, and with cemented tungsten carbide, 7000. There was, with the cemented tungsten carbide, only 5 per cent of the machine scrap that was obtained with the other tools. That is a very significant point, I think; namely, that in machining to close tolerances, the longer the life of the tool the less the machine scrap.

In reaming a malleable-iron differential carrier with a $3^3/_4$-in.-diameter hole, at 70 ft. per min. with a $^1/_{64}$-in. cut and hand feed, there were, with the old tools, one to two adjustments per day; with cemented tungsten carbide one tool had been running for eleven weeks without changing when this report was received.

With a 16-in.-diameter circular saw having inserted teeth, the increase in speed was from 900 r.p.m. to 1600. Cutting artificial floor-board material made of magnesia, asbestos, and wood shavings, the steel saw cut 80 ft. of board between grinds and cemented tungsten carbide, 1520; this represents a 78 per cent increase in speed, and an 1800 per cent increase in footage between grinds.

I could mention many more specific examples, but I think enough has already been written on the subject, and you have had enough experience of your own to know that in many instances, at least, the type of result mentioned earlier is now obtainable with the existing tools and tool equipment. There are some other features in connection with these results which I have not mentioned. In nearly every case, without change of labor, the production of the plant has been increased. It is seldom that the production is not increased 15 per cent, and in a number of cases it has actually been increased over 100 per cent. With machine tools especially adapted to take advantage of the properties of cemented tungsten carbide, much more spectacular results than those reported above have been made. Some such performances can be seen now at the Machine Tool Exposition.

The Commercial Situation

It may be said that cemented tungsten carbide received its initial publicity in the United States approximately one year ago. It is true that some of the tools from the Krupp works had been sold prior to that time. It is an interesting point here to note that fifteen months ago one tool was sold to a large manufacturer in the United States and that tool is still working, and in fifteen months it has replaced 2450 lb. of the type of tool material which was being used at the time this cemented tungsten carbide tool was introduced. But generally speaking, about one year ago the whole country became conscious that there was such a material as cemented tungsten carbide. Naturally the machine-tool builders had to make tests of their own to warrant their own expenditures in developing machines to better fit the properties of cemented tungsten carbide, and I think it is paying them

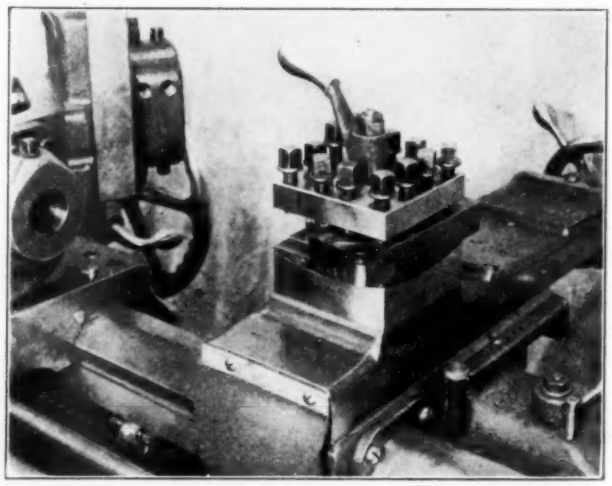

Fig. 13 Showing Rigid Mounting of Tool Illustrated in Fig. 12

a great tribute to see what they have accomplished in this short time.

With so much accomplished in one year can we not look confidently forward toward a still more rapid development?

Just a brief statement about the commercial situation. A year ago there was a clamor for tools, and for months the imported material and the material made in this country was not sufficient in quantity, or could not be made into tools rapidly enough to fill this demand. The first interest was naturally for trial purposes, and there was no great demand from any one source. The expense of trying to comply with such a demand, of course, was tremendous, and it also put quite a tax on the organizations. But all of them fought with the situation until about the middle of the past summer. Since then the delivery dates on most of the ordinary tools have been short. The same condition now obtains. There are, however, a number of tools desired by the industry which it has not been found practical or expedient to make at the present time, such as very large dies for drawing rod and tubing, but that demand will be taken care of in the not-distant future.

For the past three months the various companies have been in a position to supply ordinary tools faster than the industry has desired them. Within the last few weeks, however, the demand has increased to a point which is taxing the producing organizations.

The advent of high-speed steel was a great thing for not only the steel industry, but for all industry. It was a great thing for mankind. It has played a major role in our economic civilization, and it has perhaps done more than any other one development in the last twenty-five years to help make men economically independent, and to help make the expenditure of a given amount of human energy produce more of the necessities and luxuries of life. Its advent, however, did not reduce the amount of carbon-steel tools used. There are apparently today being made every year more carbon-steel tools than were made in the year 1905. I am not picking out 1905 as a depression year, but the year when high-speed steel began to have a real effect on production. In the same way we do not anticipate that cemented tungsten carbide, even though it be sold much more cheaply than it is today, will eliminate high-speed-steel or carbon-steel tools. I strongly suspect that in, say, 1935 there will be more high-speed steel made per year than in 1929. Furthermore, we do not regard this material as a cure-all for everything in the tool industry. Some applications have met with very indifferent success, and some attempted applications can be branded at the present time as absolute failures.

Future Possibilities

We do not know where this material will lead us, especially from the standpoint of tool substitutions. We are learning, and you are learning, and when we put all of our knowledge together we are going to find out what is economical and what is not. It seems to me, however, that we have gone far enough so that we can say definitely that cemented tungsten carbide is destined not only to have a definite place in the future of industry, but a most important place. That it will be used in large quantities and for a great variety of purposes in the future there can be no question. One of the results is going to be the enhancement of the high-speed-steel and stellite era toward greater economic benefits for mankind. It seems reasonable that the material offers the possibility of increasing, on the average, production in machine shops to the extent of 20 per cent, or will make possible the production in five days of what now takes six. If so, it must benefit all of the people, because machined goods will cost less. It will benefit the metal industries because more metal can be used, and more metal will be put into shavings and turnings than is done at the present time. Machining enters the field of competition in the shaping of metals with an improved tool, hence it is only natural that a larger percentage of the shaping of materials will be done by machining.

In closing, I should like to mention the important part played by the Machine Shop Practice Division of The American Society of Mechanical Engineers in connection with the commercial exploitation of cemented tungsten carbide. Last December, they formed a committee known as the Special Research Committee on the Cutting of Metals, and at the Rochester meeting they presented a report entitled, "The Present Status of Tungsten Carbide as a Cutting Material." That report not only very accurately reflected the status of the industry at that time, but it contains some very important and far-reaching suggestions for the activities of the Society and for the guidance of the machine-tool industry. Your Division has taken a leading part in the dissemination of knowledge on this subject, in the appraisal of possibilities, and has presented the information in an accurate and dignified manner. I wish to compliment it for the part that it has already played in connection with this industry, and I hope that it will continue to take as active an interest in the future as it has in the past.

Discussion

Roger D. Prosser.[2] Since the development of cemented tungsten carbide by the Krupp Works and its commercial introduction in the latter part of 1926, there have been produced by Krupp more than 500,000 Widia cutting tools and tips. Cemented tungsten carbide is now obviously long past the experimental stage so far as cutting tools are concerned. It is working successfully and is indispensable in many shops throughout the world.

The realization that better machine tools will be necessary to utilize fully the possibilities of tungsten carbide tools has been an incentive to machine-tool builders throughout the world, and new and better machines, especially designed to use the new tools, are appearing from day to day.

The remarkable increases in cutting speed, with corresponding increases in production, and the greater length of time between grinds, made possible by these new tools, are too well known to need further comment. However, the final result of the installation of a large number of these tools will doubtless be of interest. A number of shops are fully tooled up with Widia, and have increased their entire output over 100 per cent. This increase could only be attributed to Widia, as no new machine tools were purchased and no additional labor was employed. This remarkable result can better be visualized by considering that with a shop only half as large as before, with only half the number of machine tools and only half the number of workmen previously employed, they would still be able to produce the same output as before through the use of Widia tools.

In the introduction of any new material of this nature it is, however, inevitable that there will be some who will not at first secure the best results for various reasons. Most of the early troubles have now been overcome through efforts of the manufacturers in conducting extensive campaigns of education in the proper use and application of these tools and through the care and intelligence of the users themselves. The practical men in the shops have come to realize that cemented tungsten carbide is not a cure-all for every trouble as some had supposed at first, but rather a splendid high-speed tool by which production can be remarkably increased, provided it is used under the proper conditions.

They now realize that the toughest job in the shop is not necessarily the best place to judge the performance of the new tools, as the greatest savings may often be made elsewhere. They now understand that cemented tungsten carbide tools must be ground to certain angles to secure the best results, and that a design which may be suitable for high-speed-steel tools may be entirely unsuitable for tungsten carbide. They have learned that there is nothing mysterious about the new tools, and that if they are given good, strong tools with plenty of cemented tungsten carbide on the cutting edge, together with a good, rigid machine with ample power, they can duplicate the remarkable performances they have seen demonstrated. They realize that it is necessary to consider carefully the characteristics and limitations of the material and its difference from previous cutting metals, and to determine intelligently its proper application. They have seen the great benefits that others are obtaining through the use of these tools, and are seriously trying to determine all the places in their own particular shop where they can be employed to advantage.

The shop men have passed the stage of trying to buy cutting

[2] Thomas Prosser & Son, New York, N. Y., American representatives of Fried. Krupp A.-G., Essen, Germany.

tools by the pound. They realize that tungsten carbide tools have an economic place in industry, and they must be judged by what they will do, not by what they cost. Diamonds have a definite place in certain machining work and we seldom hear of a complaint because they cost $35,000 a pound. They are judged by their performance.

Some of the most important points to be remembered when using Widia tools are given below. They have been stated several times before, but will bear repeating.

Cemented tungsten carbide is comparatively tough when its great hardness is considered, but it is nevertheless only about half as strong as high-speed steel. This means that pressures which are suitable for high-speed-steel tools may be too great for tungsten carbide tools. Likewise conditions tending to result in pressures away from the supporting steel shank are to be avoided.

Machines should have plenty of strength and rigidity where needed to eliminate vibration and chatter as far as possible, and to support the tool properly. Ample power is also essential.

Machines should not be stopped with the tool in the cut and the feed on. This will not always break the tools, but there is great danger of doing so, just as with high-speed-steel tools.

Tools with larger shanks than usual should be employed, to give adequate support to the cutting edge, without danger of bending or breaking. Large, adequate cemented tungsten carbide tips should be used, as a large tip rapidly conducts the heat away from the cutting edge. However, the price of the tools tends to encourage the use of as small a tool as possible, which is an undesirable condition, and where heavy work is to be done, economizing in the size of the tool will result in disappointment. The purchase of a large, strong tool with an adequate tip will be found to pay in the long run.

Cemented tungsten carbide is a high-speed material. Its advantages can best be obtained by increasing the cutting speed in the proportion recommended by the manufacturer for the specific material being machined, and maintaining the same (or lighter) feeds used with high-speed steel. It is not intended for work with slow speeds and heavy feeds.

Proper tool angles, as recommended by the manufacturer, should be carefully observed for each particular material being machined. This is more important than in the case of former cutting materials

Careful grinding in accordance with instructions is essential, and the smoothness of the cutting edge has a very important bearing on the performance of the tools. The tools should be ground with proper clearances beneath the cutting edge, using the side of the wheel. Grinding clearances on the periphery of the wheel often gives a greater clearance than is apparent, greatly weakening the tool and shortening its life.

Cemented tungsten carbide tools seem destined to play a very important part in industry. The wonderful hardness and wear- and abrasion-resisting qualities of the material make it suitable for many applications which have up to the present time hardly been touched due to the urgency of the more important cutting tools. Such fields as surfaces for gages which must withstand abrasion, bushings and guides for constantly moving parts, punches and dies, bearings for scales and electrical meters to replace jewels, machinists' hand scrapers, grinder centers, and a host of similar applications too numerous to mention, are fertile fields for experimentation and offer large uses of cemented tungsten carbide. The application to drills, reamers, and milling cutters has endless possibilities, and even the cutting-tool applications have hardly been touched. In many large shops where there are at present only a comparatively few tools in some of the most important places, there are innumerable applications throughout the shop where tungsten carbide tools will show large savings. Many concerns are working with all possible speed to determine these places, so as to be able to reduce their costs ahead of their competitors.

Such facts can only mean that the development of cemented tungsten carbide tools is one of the milestones along the road of high-speed production.

R. E. Flanders.[3] The illustrations shown[4] of intermittent cuts on large work, particularly having the tools on the end of long extended tool holders, rather surprised me. I should like to inquire whether the cutting material has improved in the last few months or whether it is all due to the way in which the tool holder is held in the end of the long ram.

Dr. Jeffries. The work referred to by Mr. Flanders was done in the Crocker-Wheeler plant, and they did nothing but increase the rigidity of the tool. This was effected by increasing the size of the shank, and the size of the piece of cemented tungsten carbide itself, and by so mounting the piece in the shank that it would receive a maximum of support in portions which ordinarily would be in tension.

Mr. Flanders. It would appear from what Dr. Jeffries says that it is the very short-period vibrations that are destructive rather than the long-period ones. The long overhung ram would have a long period of vibration, whereas the stiffness of the tool and its support close to the piece of metal itself deals with short periods of vibration. That is evidently something for machine-tool designers to keep in mind, because it would seem—something along a similar line—that vibrations due to inaccuracies in gear teeth might be of fully as much importance in preserving the sharp edge of the tool as would the main structure of the machine itself.

W. D. Snyder.[5] Dr. Jeffries showed a photograph of one of our boring mills on which a carbon packing ring was being machined. This job formerly took about six hours, due to the necessity of regrinding the tool and the impossibility of holding the size during the complete cut. We now do the operation in about forty minutes with a Carboloy tool and the finish is much better.

G. N. Sieger.[6] Our experience in taking high-speed finishing cuts on steel has been both positive and negative, for no reason that we can assign. We attribute it to ignorance in the art. We have found, though, that the Carboloy cemented tungsten carbide seems to serve much better if a cut of, say, 0.015 in. is taken at a very high speed, rather than one of, say, 0.003 in. as a finishing cut.

Mr. Flanders. In lathe work where we are doing multiple tooling it quite often happens that we have a large flange at the end of a long shaft, or a large collar in the middle of a forging that may be two or three times the diameter of the main part of the work. If we could use high-speed steel tools on the smaller diameters of the piece on a finishing job and a Carboloy tool on the large flange and run it at the appropriate speed for the high-speed steel tool on the shaft end and let the Carboloy take the brunt of the high-speed work on the flange, we could speed up production on the whole job at a minimum expenditure for Carboloy.

S. L. Hoyt.[7] On journal bearings for large motors very light, thin shavings must be taken, leaving the surface of the journal

[7] Research Laboratory, General Electric Company, Schenectady, N. Y.

in almost a polished condition. We have tried these tools on that job repeatedly, but never have we succeeded in getting across even one bearing, whereas the high-speed tool would do at least one. I do not believe with Mr. Sieger that a heavier cut at high speed could be used on account of the heating effect, but I cannot but believe that that particular problem will some day be overcome when we learn more about the art of applying the material.

H. D. HALL.[8] We find in some cases that we do not get a finished bore on cast iron or malleable iron with a Carboloy tool.

MR. SIEGER. We have had no trouble recently in the finishing of cast iron or malleable iron. The answer is rigidity and high speeds.

W. S. HUSON.[9] Many of those present will remember when high-speed steels were first introduced and how the same question arose as to the finishing cut. We could not get a finishing cut with high-speed steels, or, as the material was called in those days, air-hardening steel. We do get it today. Now we can get a finishing cut with Carboloy tools provided they are shaped properly and the machine tools are rigid, so reaction on the cutting edge is not excessive. We can then get almost as smooth a cut as a diamond would give, provided work is put on the cutting edge of the tool and held there. It is in a measure about the same as with a twist drill. We know very well that many drills are dulled on the edges by racing around at the bottom of the hole rather than by being pushed right into the material and taking stock out.

C. S. GOTWALS.[10] We have had some experience with Carboloy parting or cut-off tools in an automatic screw machine on a high-carbon chrome steel, and have had no success whatever in using it. I should like to know whether any one has had any success in the use of a cutting-off tool with that material.

MR. FLANDERS. Cutting-off tools are very liable to get caught and break off, owing to the chips clogging on the side of the cut after they get into depth a little way. It is probable that the high pressures to which cutting-off tools are subjected would make it inappropriate to use tungsten carbide for them, and the edge would probably crumble.

What Information Does the Machine-Tool Buyer Need From the Machine-Tool Salesman?

By GEORGE T. TRUNDLE, JR., CLEVELAND, OHIO

THE subject assigned to me by the chairman of the Program Committee, and on which I agreed to talk, is: "What information does the machine-tool buyer need from the machine-tool salesman?" But after studying over my experience as an adviser in the purchase of large quantities of machine tools, I am going to take the privilege of setting forth some of the things that the machine-tool salesman needs from the buyer in order to serve him best.

"Who, What, When, Where, Why?"

The Cincinnati Enquirer recently published an article headed: "Who, What, When, Where, Why?" in which it was said that the first rule a newspaper reporter learns is to answer five basic questions in the lead of his story—"Who, What, When, Where, and Why?" This, the writer asserts, is a good rule for all people in buying goods. In the answers to those five questions lie the fundamental facts one should know about every article he purchases.

Under "Who" are included these questions: Who made it? Is he reliable? Is he experienced? Will he be in business if the article needs repair or replacement?

"What?" What will the article do for you? Will it improve your appearance? Will it save you time, money, effort? Will it make you more confortable, more happy?

"When?" When was it made, designed, packed? Is it fresh? Is it the newest model or latest development?

"Where?" Where can you buy it? Does your own store carry it? If not, can you place dependence on the store that does?

"Why?" Why should you buy it in preference to some similar product? Is it superior in design, materials, workmanship? Will it fit your needs more closely?

It seems that this little article covers in a few words my entire subject. While the writer in *The Enquirer* is discussing things one ordinarily would buy in a department store, the rule is good for the buying of anything; at least I hope to prove such to be the case.

What the Buyer Wants to Know in Purchasing Equipment

In the purchase of equipment: First, the buyer wants to know that the machine tool is made by a reliable firm, reliable financially as well as in ability to design and build.

Second, he wants to know that the machine is not an infringement on some one else's patent. I consider it humanly impossible for any manufacturer to say that his product is free from infringement. Therefore, the manufacturer of this machine must be financially able to protect the buyer. The buyer also has additional security if he is buying the machine from a reliable agent.

Just recently the higher courts ruled that a certain manufacturer was infringing on a patent and that he must pay a given amount of money for every machine he had manufactured and sold. It developed that the manufacturer was not financially able to meet this demand, therefore the matter was up to the buyer. Fortunately the equipment had been purchased through a reliable agent or distributer, a company which stands ready to protect its customers and which therefore paid the claim. This is one advantage of buying through a distributer rather than a direct representative of the manufacturer. Later I shall point out why I consider it better to buy through a reliable distributer.

Third, the buyer wants facts as to what can be expected from the machine in the way of production, based on facts furnished by him.

Fourth, he wants to know what delivery he can expect. The third and fourth items are the first which start argument between the buyer and the seller. Seldom does a machine-tool salesman get sufficient information from the buyer to intelligently state what production can be expected.

The production from any machine of the best design depends on the type of holding fixtures, the type of tools and the kind of material the tools are made of, the heat treating of these tools, the ability of the buyer to properly sharpen the tools, the skill of the set-up man, the skill of the operator, and the kind of cutting compound.

The salesman is often given a blueprint of the part to be machined. The blueprint will call for $^1/_{32}$, $^1/_{16}$, or $^1/_8$ in. finish. It may be a forging, it may be a casting. The casting may be hard, it may be soft. It may be full of blowholes or hard spots. The same thing may be true of the forging. It may not have sufficient stock for finish or it may have two or three times the amount specified on the blueprint. All of which has a direct bearing on the production that can be expected from the machine tool you are going to purchase.

The prudent manufacturer will make his estimate of production conservative. The reckless machine-tool salesman will assume all conditions ideal and guarantee a much higher production. The buyer is after production. He will purchase the machine promising the greatest production, or a fight, whichever you want to call it.

In the latter case the salesman has not misquoted. He is basing his facts on a blueprint which specifies ideal conditions. The buyer should, whenever possible, let the machine-tool salesman see the job for which he is buying the machine, and should give him the history of producing that part to make it suitable to be used in an assembly.

Hardly any two persons agree on the type of finish a certain part should have. The finish that is satisfactory to one may not be satisfactory to another. The drawing may call for 0.0003 in. tolerance on a reamed hole, when in reality the buyer is manufacturing the part within a tolerance of 0.002 or 0.003 in. and it is perfectly satisfactory.

As a warning to the buyer: Give the facts to the machine-tool salesman. If you are buying a machine to machine a part in accordance with the blueprint, you must expect trouble.

---

[1] Trundle Engineering Company.

Address delivered at a meeting of the A.S.M.E. Machine Shop Practice Division, Cleveland, Ohio, September 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Referring to the fourth item: The buyer wants to know what delivery he can expect. The machine-tool salesman is called in and is given the particulars and told when he must deliver the machine. The salesman is selling on commission in most cases. He wants the business. The chances are that if he tells you the truth he will not get the business, so he agrees with your delivery, or as nearly to it as he can without getting too far from the truth.

Fifth, the buyer wants to know the range of feeds and speeds. He wants to know whether his standard equipment, such as arbors, chucks, fixtures, etc., will fit the machine. He wants to know in considerable detail the size and design of the spindle, what kind of bearings, what kind of gears, whether the machine is motor driven, belt driven, or a combination drive. He is particularly interested in knowing whether sufficient power can be applied through the belt or chain to operate the machine at its capacity.

One of the most important things he wants to know is whether the machine is properly lubricated.

Previously I have pointed out to you mechanical facts, all of which pertain to the product the salesman is presenting to the buyer.

The manufacturer of a machine tool and the agent handling machines must take more care in choosing the men for their sales departments. I find the salesman whose previous training has had to do with production and engineering is much more capable of presenting his wares in a convincing way than is one who lacks this training.

Service and Advice Required by the Buyer

The buyer of machine tools has grown into the habit of expecting free engineering advice from the machine-tool salesman, not necessarily engineering advice pertaining to the particular problem for which he is interested in buying the machine, but on general machining problems. The salesman representing the manufacturer of a machine tool is usually not so well equipped for this—because he handles only one type of machine or at the most two or three—as is the salesman representing the agent who is handling a complete line of machine tools along with a variety of labor-saving devices.

Personally, if I were buying for a manufacturing plant I should prefer dealing through a reliable agent, for the same reason as outlined in a talk by J. A. Smith, general superintendent of the General Electric Company in 1927; namely, that in one interview I could get information I desired on a lot of machines rather than on just one particular make. Again, I have found that the salesman for an agent will in most cases recommend another make of machine in preference to the one he is handling if he feels that the other machine is more suitable for the buyer's needs, as this puts him in a better standing with the buyer and strengthens his chances of getting the part of the business for which his equipment is best suited.

We are constantly called on by manufacturers to make a preliminary manufacturing set-up of a product (this product may be old or it may be new with the client) to show the cost of the product when using the most modern machines and methods, as well as the capital expenditure necessary to make such a set-up. If the product is something they are now manufacturing, we take into consideration the trade-in value of the equipment. We also take into consideration the amount of money that has been written off in the depreciation account to find how the old machine made out.

When Rebuilt Machines May Be Substituted for New

In a set-up such as this we very often find it a good policy to substitute rebuilt machinery for new on some operations in order to get the difference between the costs of the rebuilt machines and the cost of new machines to apply on some machine for a major operation. In this way we are able to purchase equipment that would not be possible otherwise.

In making such set-ups we are able to save the client many thousands of dollars by dealing through a reliable agent because of the following reasons:

First, the agent, because of the size of the order, will make more liberal allowances on the used machines.

Second, the agent usually maintains a modern rebuilt-machine department and therefore can furnish rebuilt machines under guarantees equal to new machinery.

Third, the agent is located in the vicinity of the buyer's plant and is in position to render service that it is difficult to get direct from the factory unless the factory should have an office in the vicinity of the buyer's plant.

Fourth, the agent, because of his relation to the manufacturer, can usually get more attention in deliveries than the buyer would be able to get if he was dealing direct with the manufacturer.

Please do not get the idea that I am prejudiced in favor of agents or am attempting to "sell" their plan. I am giving you this information as my experience and as something for you to think about.

Fifth, because of the salesman representing the agent having come in contact with such great varieties or complete lines of machine tools, he has an opportunity to observe many clever cutting tools, jigs, fixtures, and sequences of operations that are always interesting to the buyer and thereby to help him to reduce his manufacturing cost. These salesmen are wide awake for opportunities to be of service to the buyer.

As an illustration: Just recently a salesman from one of the large steel companies came into my office with a part made from his steel and described how slow and costly the operation of making that part from his material, or any other material, was. His question was: "Mr. Trundle, is there not some machine that will do this job better than they are doing it?" I referred to our catalog file and gave him the name of a manufacturer who made a machine that would perform the operation ten times faster than the makeshift methods used by his customer. I know that this salesman went direct to his customer with the information he had secured. I am sure that the next sale of steel to this customer will be easier. I like to call this "intangible service."

When Should Machines Be Replaced

Last Sunday night, on the National Limited, three men sat in the club car discussing business and private affairs in a tone of voice that other occupants of this car could not help overhearing. One of these men, I judged, was about 50 years old, well dressed, smoking a good cigar, and with every appearance of being prosperous. The other two were perhaps between 30 and 35 years old, looked prosperous, and seemed pleased to be in the company of such a distinguished gentleman. It was not long until the conversation revealed that the two younger men were salesmen and the older man was apparently at the head of some industry which used machine tools, or at least some sort of mechanical equipment. The older gentleman made the statement that it was his policy never to buy a machine of any kind nor make a mechanical improvement unless the cost could be saved in one year.

Most of you at this meeting today have heard that statement made by a buyer, whether the buyer is a purchasing agent or the president of the company. They apparently mean what they say, but you know and I know that this great, prosperous industrial United States was not built up on that kind of reason-

ing. The buyer who has as a fixed policy and lives up to it that he will never buy a piece of equipment unless it pays for itself in one year or less is losing money and is headed straight for bankruptcy.

When I hear the statement from some man that I know to be at the head of a given organization, I immediately call on Dun's for a financial report on that company. If the report reveals that the company's profits are decreasing, I consider the man was telling the truth. If the report reveals their profits are increasing, I know he is not telling the truth. I want to make the statement that not more than 10 per cent of the machine tools sold pay for themselves in less time than two years.

Some time ago *The American Machinist* made a survey of several thousand shops which revealed that 44 per cent of all machine tools were over 10 years old. These machine tools have now grown three years older, and no doubt a large percentage of them will produce a certain kind of product at as low cost as would the most modern machine, therefore the manufacturer need not worry about how much they are digging into his profits. But the great majority are reducing his profits to a point where it will eventually be serious.

Many industries are finding it difficult to meet competition, with the result that their business is gradually tapering off. Most of these firms conclude that they are not in a profitable field because of the competition. Their competitors may be underselling them only 5 or 10 per cent, but for them to meet this cut would mean a direct loss unless they improve their planning and manufacturing methods, and install modern equipment.

Just recently I made an investigation of two products, the demand for both of which, I was informed, was gradually decreasing. Government statistics, however, showed that there had been a gradual increase since 1914, the date to which we decided to refer. The manufacturer of these articles had sought a new field by adding other lines which required considerable engineering plus new equipment and the expenditure of large sums of money to break into the market. Had he put forth the same effort on the old product and spent half the amount of money improving it and bettering his factory conditions, he would have been in a strong financial position today rather than sitting in his office with a long face wondering whether something unforeseen would happen to carry him out of his difficulty, or whether he would lose everything.

Liquid Depreciation Reserve for Replacing Equipment

I have advocated for many years that a manufacturer keep his reserve for depreciation of equipment in liquid form so that it can be used in replacing a given piece of equipment when it has reached the end of its usefulness, or better, when it has ceased to be a money earner. If something should happen to bring this about, the machine-tool manufacturers would have to expand to produce enough machine tools to supply the demand, instead of having a few years of prosperity and a long period of no business, as has been the case in the past. The fact of the matter is that the average manufacturer is transferring his reserve from his machinery account to working capital and expansion, and using all of the profits to pay dividends. In other words, he is automatically spending the tangible assets of his business.

One of the things the buyer wants from the machine-tool salesman, but does not know it, is a continuous sermon on the subject of using his reserve for depreciation to keep the plant equipped with modern machine tools.

Most manufacturers write their machine tools off at the rate of 10 per cent per year. At this rate, at the end of 10 years the machine tools have been paid for, and they should have the money available to purchase new tools. A manufacturer operating on this basis might be able to say that the machine tool will pay for itself by the first year's savings, because the cash outlay is only the difference between the price of the new machine and the amount in reserve for depreciation, plus the trade-in value of the old machine, which will be a small amount in most cases.

In closing I want to say that the machine-tool manufacturers who are preaching modern equipment to their prospective customers must install some of this more modern equipment and modern methods in their own plants and not operate on the theory that the reason their costs are high is because labor is not efficient, for labor is just as efficient as management plans for it to be. The workers are just as efficient as the tools the management gives them with which to work. I have yet to find where excessive manufacturing costs can be attributed entirely to labor.

In summing up, let me urge that the machine-tool manufacturer and the agent train their men to talk, first, on Who, What, When, Where, and Why; then if they know of a few stunts they have observed or worked out in other plants, the buyer is usually glad to hear of them, as that is profitable knowledge.

At this point it is always advisable for the salesman to introduce his little sermon on the amount of money in reserve for depreciation and the resale value of the old machine. If he can only get the buyer to realize that he should at all times have available the cash that has been written off for depreciation to replace each machine in his plant when it has ceased to be a money maker, he has then performed a real service to the buyer, and, in addition, has become much more valuable to the company he represents as well as to himself.

Discussion

J. S. Chafee.[2] I have found in my limited selling experience that one very rarely contacts with a man who has much to do with reserves for depreciation. We should be glad to have that reserve liquid as much as the salesman would. I wonder whether any one has any idea that the salesman would be able to influence the buyer's accounting methods and management so that he would have his reserves liquid rather than tied up. I think it will have to be done in a broader way than through the salesman, and that it is perhaps at management meetings as well that this will have to be preached. As I see it, the average salesman does not have much chance to influence the buyer's accounting arrangements.

John McGeorge.[3] We hear a great deal about depreciation being written off. How many firms represented here tonight really do that? When we balance the books, does not the great bulk of the balance go either to profit or loss, and is not profit and loss at once divided among stockholders? Is there any real depreciation actually provided for? In other words, is the money that depreciation represents actually put in the bank or not?

Mr. Cochran.[4] In our company a machine does not become obsolete until the machine-tool industry has brought out a machine that will displace it, because we keep our machines in first-class condition and they are not obsolete until something has been produced that will make our goods faster.

---

[2] Assistant Secretary, Brown & Sharpe Mfg. Co., Providence, R. I. Assoc-Mem. A.S.M.E.

[3] Consulting Engineer, Cleveland, Ohio. Mem. A.S.M.E.

[4] National Cash Register Company, Dayton, Ohio.

R. E. Flanders.[5] Some five or six years ago a formula was devised by the Materials Handling Division of the A.S.M.E. which answers all these questions that have been put here tonight. Last fall Professor Roe applied it with some slight modifications to the obsolescence of jigs and fixtures—how much we could afford to spend for them.

Alfred E. Beulow.[6] There seem to be quite a number of manufacturers who only use tools that cannot be purchased from distributers as maintenance or equipment to make tools with, so that I cannot quite conceive of the idea that the local distributer would be the man to go to in most cases—perhaps in standard cases.

C. O. Malpas.[7] In order to conserve effort the buyer is in a position to call in an agent representing several lines and he has the possibility of securing all that he wants in one interview, whereas if he has to call in the direct manufacturer, he will probably call in four, five, or six different persons in order to get the complete list of equipment that he needs.

Mr. Beulow. It seems one cannot get all the information he requires from one distributer, because distributers mostly are handling machines along one type. For instance, one manufacturer who is making a certain product no doubt can use standard machines, but certain other products require special machines that have no local distributors.

Mr. Malpas. The agents in your vicinity may not handle the particular tool that you want or it may be a special tool, but they may be in position to get that information for you if they are alive, want the business, and want to give you the service and sell you something that they actually have.

Wm. J. Burger.[8] In my limited experience I find that the only information you get from the agent is the information you can pick out of the circulars. If you really want to know something about the machine you must get the representative from the factory or write.

I do not believe there is any one that can rebuild a machine other than the man who built it. If any one else tries, he will make a mess of it, and no one wants that type of rebuilt machine.

I do not think any one is in better position or can give you the service you want than the manufacturer. When it comes to giving information about the performance of the machine that he is offering, the agent knows very little about it.

George F. Johnston.[9] In my experience in buying for a large company in Wisconsin I have found that the agent that we have dealt with directly in many cases has not had the information that we needed, and in stating and showing him what we needed he has had to write back to the factory to get this information, which has caused us a great deal of delay. That has been true not only in one case but in very many cases. We find that we are better able to serve the trade by knowing our particular machine and knowing what production one may obtain from it, and the feeds and speeds that can be used and the type of fixtures. We also have to furnish a great many special heads, and we find that the agent cannot answer the questions of the buyer intelligently and offer him the service of quoting directly and giving him the production figures unless he is versed on that particular machine.

Harry Barney.[10] From the little experience I have had and from what I have heard it seems that the sale of machine tools for many years gone by has been handled quite ably through dealer distributers. On special equipment, jigs, fixtures, etc., I agree that in many cases it is desirable and advisable for the manufacturer to be brought into the picture, but the dealer's salesmen are supposed to know something about the equipment they are selling. They have made an analysis of it, have spent time at the manufacturers' plant, and should be in position to know intelligently the materials that are in the machine, its productive capacity, and so forth. They are in contact with the trade every day, and know the speeds and feeds that can be maintained and the type of cutting tools that can be used to the best advantage.

As to the matter of trade-in, I believe that after a machine tool has served its purpose, it should be scrapped, and not put on the open market.

W. W. Nichols.[11] The manufacturer is called upon to give guaranteed times of production, but if the salesman were to stipulate that that guarantee was to be performed on the manufacturer's material, in the machine-tool manufacturer's shop, before delivery was made on that machine, and not left to the idiosyncrasies of some shop foreman who perhaps does not want the machine in the buyer's hands, considerable discussion would be eliminated.

E. C. Brandt.[12] Why do we get something into our minds, order it, and then want it the next day? When we get an idea, what is a reasonable time to expect a realization of that idea?

Mr. McGeorge. Why should there not be the middleman between the user of the machine and the manufacturer, just as there is the architect between the owner of a building and the builder?

There came into my own practice not very long ago this situation: I was in a Western city, and one manufacturer I know had given orders that all material should be purchased in that city. When I went through the factory I noticed that the machinery they had had been bought in Detroit and in Cincinnati, but was told most stoutly that that was bought in Los Angeles. I said to him: "Why didn't you call on me, I could have found you at least three establishments right here in the city where they had every pattern required for this work," and I told them just where they were. He said, "We called upon those very firms and they said that they had not sufficient particulars." Now there was an argument that I should interpret as a need for a consulting engineer.

Thomas R. Jones.[13] What does the buyer expect from the machine-tool salesman? Why does a buyer buy a machine tool? For production? Yes. There are a great many things he buys it for, but in the last analysis he buys it to produce something in a manner that will add the greatest amount of profit to his profit and loss statement at the end of the year.

Now if the salesman is to know the economics of that machine tool, he must know something of cost accounting, the allocation of costs, how to allocate costs of floor space, of machine tools; what depreciation means, what determines the replacement of that machine.

The salesman must have at his fingertips the points which will give the buyer the information which will enable him to set up his own information as to what that machine will cost him in the long run, or what its production will net him. In many cases the buyer does not know how to figure his costs, and it may be necessary for the salesman to do something in the way of assisting him.

L. Baker.[14] I come from one of the small concerns that look with envious eyes upon the large ones that make big savings by using high-production machines. We want to use them, too, but we cannot because we do not produce enough parts of any particular kind. In order to find out whether we could use a machine of any particular type we should have to look more to the versatility of the machine, how it is set up and how we can set it up, how many times we can set it up and still make a saving through small production, and that is a thing that we invariably ask the machine-tool representatives who call upon us, and it is almost invariably the thing that they know little or nothing about.

W. G. Thompson.[15] As regards service from jobber-dealer compared with that from the manufacturer, in our plant in Racine we are producing tractors. The last year and a half we have spent a considerable amount of money on new equipment of various kinds. At first we called in the dealers and jobbers in that section who handled these various machines, and salesmen would come in and make a few remarks, ask a few questions, and take a blueprint. In two or three weeks they would come in with but half the story, and would have to go back for a representative from the factory. The eventual result was that finally they brought along the representative from the factory the first time.

As to cost of replacement: As long as a machine will produce as economically as a new one would, it should be kept in service, provided its upkeep and repairs do not forbid.

W. J. Peets.[16] In the matter of delivery of machine tools, if we have a production schedule a couple of weeks off and have been promised an eight-weeks delivery which stretches to three months or more, it makes us much angrier than if we had been given the three-months delivery in the first place and had made some temporary arrangements for handling the operation until we got the machine. Nothing is worse than delayed deliveries when a production schedule must be met.

A machine should bring some return in a definite time and should be bought on that basis regardless of whether there is money in the obsolescence account or not; if it is warranted by what it will produce, it should be bought. If a machine is a general machine that will not be put out of business by changing your product, you can take longer to pay for it than if the machine is entirely special. You have got to consider the amount of time that your product will continue—it may be two or three years or four years—but if it is a general machine it may run for five or six years and still be a good investment; it depends entirely on the machine and what is going to be done with it.

Mr. Pflume.[17] For fifteen years I represented the Heald Machine Company in Cincinnati. For a year I have had a number of lines that I now represent as a manufacturers' agent. I find that the manufacturers of machine tools do not give their representatives enough information. Men who want to buy machines talk in terms of cross-sections, of blueprint—they want to see the inside of the machine or device that is going to give them $5 where they are only getting $1.

Invariably circulars are made up largely of photographs and it is rarely that one can discern from a photograph a detail. We do not make machinery from photographs, but from line drawings, from cross-sections, from details, and every man buying machine tools understands cross-sections and details. If you had a blueprint to scale with a few dimensions on it, then you can talk the language of engineering, and the business of selling machinery today is engineering.

Mr. Cochran. One of the discussers has spoken about the manufacturer's direct representative being able to give information more quickly than the dealer. I am going to challenge that statement. If I want production estimates, the machine-tool dealer can get that information from his plant just as easily as the direct representative of the manufacturer, because the latter has to go to his production engineering department to get that information. At the same time that I am getting information on one subject from the dealer I may get it on another subject provided he is not a salesman but a sales engineer.

A direct sales representative has to cover more territory than a dealer does and he always seems to be at the other end of his territory when we want information—which makes it necessary for us to deal directly with the plant.

George B. Blaisdell.[18] The policy adopted by the engineering department of our company for replacing equipment is as follows: Before we can buy a new machine we make a comparison of the cost of the present machine with the cost of the new machine, on a general basis. We take into consideration the depreciation on the old machine as set upon our books; the depreciation of the new machine as we estimate its life. Then we take the obsolescence, the depreciation on the old machine and distribute it for the life of the new machine. We next take into consideration the repairs of the old machine as found upon our books, and estimate the repairs and maintenance of the new machine. We then take the cost of tools—so many dies or a certain number of tools per year. We figure that cost in to the yearly cost of the operation. The next item is labor, for in most cases in a hand operation it requires more labor than in machine operation. Next compare the power cost. We total these up and get the yearly cost of the present machine, and the difference between the two is our saving by purchase of the new machine. Divide that by the cost of the new machine and get the percentage saved, and if it is not more than 25 per cent we do not consider the purchase of the machine. It has to pay for itself in at least four years.

Mr. Hathaway.[19] Our work is largely standard and largely specialized. When we lay out a job for a customer we like to send blueprints and have them approved. We sometimes wait a long while to get them back, but the customer waits just as long to get his machine. That is a point I want to bring out that the customers want our machine in a hurry, but will not send us the information in the same hurry.

R. H. SMITH.[20] I think we owe a great deal to the machine-tool salesman and the sales engineer. Many of them come into factories and can tell the buyer whether he needs duplex machinery, or a multiple machine, a one-purpose machine, and can furnish him with a large amount of information which he needs. Therefore I feel that the machine-tool industry owes a great debt of gratitude to this body of salesmen. They are highly trained, and at no time in the history of the machine tool have we had such a splendid body of salesmen as we have today.

MR. HAUGEN. The main difference between the consulting engineer and the sales engineer is that the latter renders his services free of charge.

May I ask that you assist the salesman to this extent, that when he wants to sell you a new machine, you will give him some of the details of your present cost of production?

MR. FLANDERS. Conditions in America will practically make consulting engineers of some of the sales force of any machine-tool firm, or the firm will go out of business, and furthermore that service is rendered free; that is another disadvantage of it, but it has to be done in order to make sales. Often the change of a slight detail will make a job a productive one, and in these days competitive conditions require that a successful machine-tool firm shall give engineering advice, getting the cost back to a certain extent in the price of the machine. I think, in general, machine-tool salesmen have to know more, they have to give a higher grade of service, and have to be on terms of more nearly professional nature with their customers than any other line of salesmen that I know of, and I am strongly for them.

[20] Massachusetts Institute of Technology, Cambridge, Mass.

E. F. DUBRUL.[21] As to the formulas, I should expect an intelligent buyer sitting down with an intelligent sales engineer to be able to work them out, for I took all the data of the problems given in Professor Roe's paper as illustrations, put them before my little twelve-year-old daughter who did not know algebra—gave her the figures for the values represented by letters, and she knew enough of arithmetic to solve them.

I believe that we can find some way of evaluating the relative merits of the different features that are built into machine tools.

If that part of the engineering profession that is working in machine-tool engineering in a definite line, whether lathes, drills, or machines of a competitive type, applied the knowledge that they must have to be intelligent engineers to the economics of the things they are putting into their machines, they could evaluate machine tools in dollars and cents per this and per that feature, just as a fire-insurance company rates a building and charges its premium according to the type of construction, hazard, and so on which they have figured out on an engineering basis.

The problem in machine-tool engineering in pricing and evaluating both for the buying and selling of machine tools would be a more complex thing than the rating of a building where they have an experience to go by that is pooled from the records of the fire-insurance companies, but I think we can do it, and some day I believe that the younger generation that is coming up in the business is going to tackle problems of that sort and be able to find out why we should put in these things, what the worth of them is, and determine what the machine will save to the user and whether it can be built for the price that can be obtained for it from the user.

Quality Control and Production Gages

By EARLE BUCKINGHAM,[1] CAMBRIDGE, MASS.

In this paper the author discusses basic principles entering into quantity control and the use of production gages. The development of interchangeable manufacturing has many advantages and should result in economies. Considerable progress has been made by many large manufacturers. Tolerances should be as large as will result in satisfactory operation. The drawings and specifications should give tolerances. The author presents an analysis of data received from manufacturers regarding cost of inspection and percentage of scrapped parts.

INTERCHANGEABLE manufacture was discussed for many years before it was realized as a practical manufacturing system. The advantages and probable economies of making the several component parts of products such as clocks, watches, and firearms such close duplicates of each other that they might be assembled without fitting, and be interchanged from one assembled unit into another were almost self-evident. Early attempts to accomplish this consisted primarily of providing filing templets to which each part was to be matched or fitted. Thus these first examples of special productive equipment included in themselves both the manufacturing equipment and the production gages.

The inadequacy of these first crude examples of special manufacturing equipment is largely responsible for the development of most of the present-day machine tools, automatic machines, and other special manufacturing equipment. In the course of this development, as well as in the growth of the technique of this type of manufacturing, existing means of measurement were found to be inadequate. This in turn led to the development and refinement of mechanical measuring devices of many kinds. It is axiomatic that the accuracy to which work can be done depends upon the accuracy to which measurements are made because errors cannot be corrected until their nature is identified and their extent measured.

Inspection methods and the production gages used have been developed generally around particular commodities. Many measuring instruments and gages have reached a considerable degree of standardization. In general, however, the common practice is to provide limit gages for all specified limiting dimensions, and these gages are made as simple as possible without much consideration to either the relative importance of the dimension measured, its interrelation with other dimensions, or the cost of using the inspection tools. The fact that a dimension on a drawing is given with tolerances is generally assumed as sufficient reason for providing gages for it without further consideration. If drawings were always complete and precise this assumption would be correct, but the technique of dimensioning drawings with tolerances has not yet been fully developed. Considerable progress along these lines, however, has been made by several of the larger manufacturing organizations, particularly those which have extremely large rates of production to maintain.

To obtain data on normal costs of inspection, percentage of spoiled parts, etc., the author addressed letters to a wide variety of industries asking for information. All replies did not give definite figures, but some responded with comments of value. Some of these comments are as follows:

We are unable to state the proportionate cost of our product in terms of gages or inspection as we do not segregate these costs on each individual article, due to the large number of articles manufactured and the extreme variation in design.

We look upon gages and inspection in the same manner as we look upon machine tools, etc., namely, they are essential to the production of the article, and the degree of accuracy required depends, of course, upon the specific article under consideration.

Each workman, as well as tool-setter, tester, and inspector, contributes more or less in normal production to the cost of inspection. Consequently the writer is unable to give any information of value relating to gaging or inspection as proportioned against other costs, such as material, overhead, etc.

As regards percentage of scrap tolerated, our ambition is to reduce this scrap to zero, which is an ideal hardly attained in practice. We treat each article manufactured as an individual problem, and do not set any limit that might be termed allowable scrap.

Initially, with a new line of apparatus, the first consideration is not what inspection may cost, but rather that the specified performance, interchangeability, and uniformity must be met. It is the responsibility of the inspection department that these requirements shall be met with certainty. The use of gages is a great advantage, but obviously these can only be used for certain classes of work. In most cases the inspector uses the same gages that are used for manufacturing, and therefore no additional expense is incurred for the same except that of checking their accuracy. They are therewith able to inspect more quickly and accurately. This is illustrated by actual data. The lowest figures in the values given apply to the case of a product consisting entirely of machined parts using jigs, gages, etc., to the fullest extent. (Note, inspection costs without gages are about seven times as great as these costs with full equipment of gages.)

The problem of the inspection department is to perform its functions at the minimum cost. When this cost seems or is high, either due to an excessive amount of defective work or parts, or facilities for inspection or excessive variation from standard, it becomes a problem for the tool and production departments.

Whether it is cost of inspection or scrap expense, past experience in the same or a similar product, or the better performance of others, is the only dependable guide. The usual set-up is that whenever any one can show where there is an opportunity for the reduction of cost, or for a saving, their suggestions will receive consideration, and if deemed worthy will lead to a study or investigation.

The direct labor element of inspection may, of course, be a minor part of the cost of quality control. In some industries it would be small in comparison with the laboratory tests performed on raw materials; in some it would be small in comparison to the amount of product consumed in tests. Quality control, or "what price quality" is so much a part of the duty of the whole manufacturing organization, that it is impossible to estimate what proportionate share of the total cost may be attributed to it.

The amount of gaging on machine work depends on many factors. Its need decreases as the strength of the producing organization increases. It decreases with the fluency of the part in question because of the continued familiarity of the whole organization with the task. It is necessarily large where a high degree of interchangeability is necessary, or where great hazard may exist in the escape of a product not up to standard.

The percentage of scrap which one is forced to tolerate depends on what the product is, how stable the demand and therefore the organization, and many times on such elements as the weather itself.

There is some fluctuation in the figures submitted when manufacturing is continually increasing its production, necessitating the training of new men. When a factory has had production running normally for over a year, then the figures given would, in our estimation, be fair for our type of work.

The figures given do not represent the total amount of inspection work done by employees, however, nor do they cover the cost of the variety of gages used through the factory, which is considerable.

---

[1] Associate Professor, Engineering Standards and Management, Massachusetts Institute of Technology. Assoc-Mem. A.S.M.E.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The greater part of our gaging is done by the operators at the points where the different steps of manufacture occur. A large number of our employees have been a long time with the company, and many of them are specialists in the particular operations they perform. Often 50 per cent of an operator's time is spent in gaging the work he produces.

The following statistics on cost of inspection represent the per cent of payroll for inspection as compared with the total payroll factory cost of the product. The per cent of scrapped parts represents the per cent of spoiled parts because of faulty workmanship or material, as compared to the total production. An attempt has been made to separate them into groups which have very similar manufacturing problems.

CLASS A Household and office appliances such as washing machines, sewing machines, calculating machines, typewriters, telephone equipment, etc.

Cost of inspection.....	from 2 per cent to 7 per cent
Scrapped parts.....	from 1/2 per cent to 5 per cent

These percentages vary in the different departments, depending upon the nature of the production methods and the design and requirements of the components involved.

CLASS B Machine tools, electric motors, turbines, etc.

Cost of inspection.....	from 5 per cent to 7 per cent
Scrapped parts.....	from 1 per cent to 7 per cent

CLASS C Automobiles, agricultural machinery, gasoline engines, etc.

Cost of inspection.....	from 4 per cent to 10 per cent
Scrapped parts.....	from 2 per cent to 7 per cent

CLASS D Standard small tools, gages, etc.

Cost of inspection.....	from 10 per cent to 20 per cent
Scrapped parts.....	from 5 per cent to 25 per cent

CLASS E Special tools, gages, fixtures, etc.

Cost of inspection.....	from 25 per cent to 50 per cent

The cost of inspection on different types of productive equipment, even in the same plant, or different parts of the product, some simple and others more intricate, varies considerably in these figures. Thus in one plant with an average inspection cost of about 7 per cent, the inspection costs in different departments vary from 2 per cent to 29 per cent. In another plant whose average inspection cost is about the same, these inspection costs vary from 1 per cent to 67 per cent in different departments.

Even on the same type of manufacturing equipment, these inspection costs vary, depending upon the requirements of the product. For example, in automatic screw machine departments, the cost of inspection on the average product may be as low as 1 per cent or 2 per cent, while on parts with very close tolerances where the product must be watched continually, this cost may increase to over 10 per cent.

One interesting example comes from a large plant manufacturing a wide variety of products. On two similar products, the first being quite completely tooled up and provided with gages for rapid inspection, while the second has a minimum of such equipment, there are the following percentages:

	First example	Second example
Cost of inspection.....	1 per cent	7 per cent
Scrapped parts.....	1/2 per cent	7 per cent

The initial gage equipment in one plant which is completely tooled up to manufacture a specialized product represents about $10 per employee, and the cost of the maintenance of these gages is about one-tenth of 1 per cent of the factory cost of production.

GENERAL PRINCIPLES

In "Modern Developments in Inspection Methods," E. D. Hall gives the following suggestions:

Inspection in general does not create but rather controls quality. Quality is conceived in the design and given substance in the materials chosen, and form in the manufacturing operations. Given good designs and materials, the manufacturing organization must be held responsible for the construction of a satisfactory commodity.

However, the executives of this branch have many opposing forces bringing pressure upon them, such as demands for quick delivery, low costs, high earnings for the operators, and quality. Since the first three are immediate and ever present, while the consequences of variations in quality are usually more remote, it follows that the first three will receive the most attention by the branch engaged in producing, and that the supervision and control of quality because of its importance can best be cared for in a separate organization.

For the same reasons, the head of the inspection work should report directly to an executive who is far enough up the line to give due weight to quality as well as to costs and production.

It should be apparent from this summary of inspection that this function of manufacturing is very closely interwoven with both the design and methods of production employed. The progress of a commodity will be traced through all stages of its manufacture from its inception as a mechanical project to the final testing that determines its successful completion.

The development of any new mechanism starts with a mental conception of some function to be performed.[2] This conception then takes detailed form, first mentally, then on paper, and finally in metal. The experimental model, if such be constructed, is usually made by the cut-and-try method. Little attention is paid in the beginning to future manufacturing requirements. The main object is to construct a mechanism that will function properly regardless of the exact design. When this end is reached, what may be called the inventive or functional design has demonstrated its success.

Before manufacturing is begun, however, a manufacturing design must be perfected which will modify the inventive design so as to allow its economical production on a large scale. Many manufacturers recognize this twofold nature of designing, and maintain a separate department for each type. Indispensable as is the original invention, it is the manufacturing design which largely determines the success or failure of a given project. This manufacturing designing necessarily continues throughout the whole course of production because of the almost infinite number of petty detailed questions involved, only a few of which can be foreseen and answered in advance. One of the important functions of an engineering department is to keep in close touch with the progress of the work in the shops, deduce general principles therefrom, and apply these principles not only to the work in hand, but also to all new work that may be developed.

Assume that the functional requirements of the mechanism are established, and that the manufacturing design has been adopted. The first concern is to test this design as far as possible. The most certain method of accomplishing this is to build a physical model. Such a model must not be confused with the experimental model, as its purpose is quite different. The experimental model shows that the mechanism will perform certain functions. The manufacturing model, if properly developed, proves that the mechanism, as modified and developed to facilitate manufacture, still retains the functional advantages of the experimental model. The manufacturing model is naturally an expensive piece of equipment, but if a large output of a new commodity is under consideration, it is money well invested. In the case of a small total output, a "pilot" mechanism is often built for this purpose, which is not set aside for future reference but is incorporated in the product itself.

Clearances are vital factors, in interchangeable manufacturing. Fits can be secured without interchangeability, but the

[2] The discussion from this point on is taken from "Principles of Interchangeable Manufacturing," by Earle Buckingham, The Industrial Press, New York, N. Y., 1921.

latter cannot be maintained without proper clearances. It is self-evident that a certain space must be left between operating parts. The minimum clearances should be as small as the assembling of the parts and their proper operation under service conditions will allow. The maximum clearances should be as great as the functioning of the mechanism permits. The variation between a maximum and a minimum clearance determines the manufacturing tolerance. It is clear then that determining at the outset the permissible clearances establishes also the extent of the tolerances which control the final inspection.

Clearances should be one of the principal considerations in developing the manufacturing design. This design should aim to allow the greatest possible amount of clearance between companion parts. The more the design lends itself to this end, the greater the economy of manufacture, and the greater the degree of interchangeability obtainable. In determining which parts of a mechanism can be made interchangeable, this matter of permissible clearance plays the largest part. A mechanism which is designed so that it cannot permit fairly liberal clearances is not a suitable one to be manufactured on a strictly interchangeable basis with the standard equipment now available. Every operating part of a mechanism must be located within reasonably close clearances in each plane. After such requirements of location are met, all other surfaces should have liberal clearances.

The general tendency in the past has been to establish manufacturing tolerances by trying to hold the product as closely as possible to a fixed size. The natural result of this policy is that the tolerances established on paper are often exceeded, yet the actual working variations remain unrecorded because it is argued that under certain conditions the original requirements might be met, and, therefore, the tolerances noted are the proper ones, even though they are not maintained. Every effort to make the recorded tolerances represent the actual working tolerances is opposed on the ground that such a procedure would lower the shop standards. As a matter of fact, it is hard to understand how anything could lower the standards of the shop more than the absolute disregard of the rules it is supposed to be obeying.[3]

There is a further argument for the acceptance of liberal tolerances. Too often in manufacturing concerns, and especially in the case of interchangeable manufacturing, one finds details being made ends in themselves rather than means to a larger end. In producing a component part, the main object should not be to demonstrate how closely a fixed size can be approached; the aim should be to construct as economically as possible a mechanism that will satisfactorily perform certain functions. The knowledge of how accurately a machining operation can be performed is indeed invaluable in making the manufacturing design, but when that design has once been completed, interest should shift to the proper functioning of the completed mechanism. Finally, it may be said that in most cases the tolerances originally fixed are increased during the process of manufacturing without detriment to the mechanism. It is rarely that a tolerance has to be reduced.

The proper minimum clearances can be determined quite readily and definitely for most cases in the early stages of the work. The manufacturing model is of great value in this respect, but the maximum clearances become established only after extended experience with the particular mechanism. In many cases the extreme maximum is never found, because, long before that point is reached, the tolerances have become so liberal that there is no need, from the standpoint of economical production, to increase them further.

Component drawings have two main functions to perform. The first is to give such information about the design, holding points, and tolerances that the manufacture of a product can be started. This does not seem like a very difficult task, but the notation of tolerances on component drawings has created new problems of interpretation that have not, as yet, been fully solved. At the present time, the language of drawings with tolerances is not altogether clear and exact.

The first tendency in introducing tolerances on drawings seems to have been to attempt to express a permissible variation on every dimension given. The results obtained in the shop depend, then, upon the particular combination of dimensions used. Different organizations using different combinations could obtain radically different results, and of the possible number of different combinations there is practically no end.

The existence of a tolerance on a drawing is an acknowledgment that variations are inevitable in the physical dimensions of the product. Any dimension given on such a drawing without a tolerance should not be construed to denote an absolute size without error, but rather to indicate either that the permissible variation for that point or surface is controlled by tolerances given on other co-related dimensions, or that the dimension is so relatively unimportant that no attempt had been made to determine its permissible variation.

In making component drawings, the effort should be made to give the dimensions and necessary tolerances so that it would be possible to lay out one, and only one, representation of the maximum metal condition and one, and only one, of the minimum metal condition. If such layouts were superimposed, the difference between them would represent the permissible variation on every surface. Any condition of the product which fell within the zone thus established should be considered as meeting the requirements of the drawing. If one will make a few such layouts, it will soon be clear to him that there are always a number of dimensions that should be given without tolerances, if drawings are to be kept consistent and intelligible.

It must be realized at the start that it is impossible in every case to give on one component drawing all the dimensions that are needed to construct the patterns, tools, gages, and other manufacturing equipment without introducing many inconsistencies. Certain dimensions could be correct if one set of holding points and one series of operations were to be used, but might be incorrect under different conditions. If the component drawings are made so that they represent the proper completed conditions, the end in view is attained. Any figures that the shop desires to use are correct if they insure this result.

It is impossible to amplify this point without entering into a prolonged discussion of the effect of using different holding or registering points in the manufacturing processes. Yet it may be of interest to know that several manufacturing plants solve this problem by adding operation drawings, which give only the specific dimensions required at a particular operation.

[3] "Precision in manufacturing is not a thing to be set on a pedestal and worshiped. It costs money and time. Where it is necessary to the proper functioning of a mechanism it is worth whatever it may cost. In most mechanisms which require close fitting there are but few critical dimensions which need to be held to close limits. For any manufacturing operation the tolerances given should be the widest which will assure satisfactory operation, but no wider. Anything closer than that is economically unsound. It is particularly unwise to place close tolerances on a drawing, and then permit deviations by special dispensation. If work outside of established tolerances is usable, it proves that the tolerance is too close and should be widened in the interest of economy. Adherence to the established tolerances can usually be assured by correctly designed limit gages. The gages should be made inside the limits but as close to them as practicable, first cost and maintenance both being considered. They should then be used as fixed limits. The 'Go' gage should go and the 'No Go' gage should not go, and no gage should be forced, otherwise its life will be short." From "Some Limitations on Manufacturing to Close Limits," by B. H. Blood.

Some of the dimensions are duplicates of those on the component drawings, while others are computed to serve their restricted purpose. This proves an effective means of recording additional information required in the manufacturing departments, which cannot be put on the component drawings without danger of misuse.

After production is well under way, the component drawings have served their first purpose. In the meantime, the actual manufacturing operations have made available a store of new information regarding the proper conditions to be maintained. It should be the second function of the component drawings to record as much of this information as possible. Conflicting information, or misinformation, should be eliminated at the same time; in short, the drawings should be revised to agree with actual conditions and requirements. It has been a great fault in the past to neglect this second function almost entirely. It is a difficult task to make the component drawings represent from the first conditions that must be maintained. In time, the shop will discover many of them, often after bitter experience, even though they have been omitted from the component drawings. Frequently, however, it happens that this information does not make its way back to the office, but is retained by the shop men among themselves. Often this is the fault of the office, which is prone to consider such information as criticism, so that the shop, after a few rebuffs, makes no further attempt to pass it along. It is most essential, however, that such information be recorded in permanent form, not only because of its value to the work in hand, but also because of its helpful application to new work in the future.

The problem of the proper dimensioning of component drawings with tolerances is strictly a mathematical one. There are a few basic principles in regard to it as fixed and simple as Newton's three laws of motion, but even more difficult at times to apply correctly. Tolerances are necessary in commercial specifications only because of inability to produce absolutely identical parts. Tolerances should show the permissible amount of variation, and the direction of such variation that is less dangerous. When a variation in either direction is equally dangerous a bilateral tolerance should be given. When a variation in one direction is more dangerous than a variation in the other, a unilateral tolerance should be given in the less dangerous direction.

Adherence to the following rules for dimensioning with tolerances will help to avoid inconsistencies with the resulting misunderstandings in the manufacturing departments:

1 Only one dimension in the same straight line can be controlled within fixed limits. This is the distance between the cutting surface of the tool and the locating or registering surface of the part being machined. Therefore it is incorrect to locate any point or surface with tolerances from more than one point in the same straight line.

2 Every part of a mechanism must be located in each plane. Every operating part must be located with proper operating clearances or allowances. After such requirements of location are met, all other surfaces should have liberal clearances.

3 Dimensions should be given between those points or surfaces that it is essential to hold in a specific relation to each other. This applies particularly to those surfaces in each plane which control the location of other component parts. Many dimensions are relatively unimportant in this respect. It is good practice in such cases to establish a common holding point in each plane and give, so far as possible, all such dimensions from these common locating points. The locating points on the drawing, the locating or registering points used for machining the surfaces, and the locating points for measuring should all be identical.

4 The initial dimensions placed on component drawings should be the exact dimension that would be used if it were possible to work without tolerances. Tolerances should be given in that direction in which variations will cause the least harm or danger. When a variation in either direction is equally dangerous, the tolerances should be of equal amount in both directions, or bilateral.

5 The initial clearance, or allowance, between operating parts should be as small as the operation of the mechanism will permit. The maximum clearance should be as great as the proper functioning of the mechanism will permit.

If careful thought is given to these component drawings, much time and effort will be saved later in the shop. If they are neglected all the future work will suffer. A large percentage of the mistakes made in the manufacturing department may be traced back to improper component drawings.

Thus far these elements which form the groundwork for the actual manufacturing operations have been discussed. The manufacturing design has been developed; it has been tested with the manufacturing model; the first guess as to the proper manufacturing tolerances has been made, and all suitable and available information has been recorded on the component drawings. The means of carrying on the work of actual production will be passed over, and the facilities that should be provided for checking the results will be considered.

There are three reasons for inspecting the product during manufacture. First, the set-up of the productive equipment should be tested before production is started. Second, spoiled parts should be eliminated as soon as possible to save the expenditure of useless effort on unserviceable pieces. Third, the finished components must be checked before assembly to eliminate the unserviceable parts, and thus insure the proper functioning of the mechanism. For these purposes gages are extensively employed.

A gage should be provided whenever its use is more economical than the use of standard measuring instruments. For example, if the total production of a certain mechanism amounts to about a dozen units, it would be gross extravagance to provide any special gages. On the other hand, if this production amounts to several thousand units, a complete set of gages is both desirable and necessary. The extent to which gages are necessary, therefore, depends in great measure upon the amount of the total production. Furthermore, gages should be provided to check only those conditions which it is essential to maintain. The nature and extent of the gages required depend upon the manufacturing conditions. In many cases, a check on one or two points is sufficient to detect any unsatisfactory results. Under varying manufacturing conditions different faults must be guarded against. Gages are a preventive and not a cure. The point to be emphasized is that they should be provided whenever their addition will result in the production of more or better components with a total expenditure of the same or less effort.

There are two kinds of gages to consider, which for want of better terms will be called limit gages and functional gages. A limit gage is one that checks a specified dimension to specified tolerances. A functional gage is one that checks the relationship of several dimensions to insure the proper functioning of the assembled mechanism. As with other manufacturing equipment, the exact design of a gage is unimportant if it fulfils the purpose simply and efficiently.

The degree of accuracy required on the gage depends upon the extent of the tolerances on the product. In all cases, on limit gages, the variation should be inside the established limits of the component. The dimensions given on component drawings are limit gage sizes. For example, the limits given for the diameter of a shaft should be interpreted to mean that such diameter must be made to satisfy ring or snap gages of the sizes specified.

Gages are an integral part of the manufacturing equipment. They comprise that part of the equipment the purpose of which is to measure the product, as distinguished from that part of the equipment, the purpose of which is to change the form of the material or to hold the part during a manufacturing operation.

Under this broad definition of a gage, it is apparent that some of the manufacturing equipment may be not only a holding device but also a gage. In fact, it is good practice to make jigs and fixtures so that an unserviceable part cannot be inserted. It often happens that when the normal manufacturing variations of certain machining processes are small and within known limits, a gage may be employed to test the size or form of the cutting tool, and not be applied directly to the product. At other times, a gage in the form of a setting block for the position of the tool is made as an integral part of the fixture. Again, some types of grinding machines are fitted with sizing devices which stop the feed of the wheel when the work has reached a predetermined size, thus practically eliminating the need of continuous inspection. Therefore, to determine the character of the gages that are required for the production of any particular part, it is necessary to consider both the requirements of the parts in question, and the other manufacturing equipment that is provided.

The actual production consists of taking the raw material and passing it through the equipment until it emerges as a finished component. The production problems are many and varied. Any part of the preceding work which has been slighted or left undone must be completed here in addition to the many tasks which are involved in the production itself. The problem of production is essentially the same in all industries. The requirements of the product should be determined first, and then suitable means of production must be selected or developed to secure the desired results. Often the exact requirements of the part or product in question are not fully established until actual production has been under way for some time. This situation imposes upon production the additional burden of unanticipated refinements in the manufacturing operations. Such, in brief, has been the history of production of almost every commodity.

The greatest problem involved in production is that most uncertain factor, human nature. The present tendency is to provide equipment that can be operated by semi-skilled labor. Equipment, however, cannot be made altogether fool-proof. The best that can be done is to arrange matters so that little or no excuse remains for making mistakes.

People thoughtlessly speak of unskilled labor. The more this problem is studied, the more it is realized that there is no place in interchangeable manufacturing for such assistance. That is, there is no task so elementary but that better and more economical results can be obtained by a certain degree of training or skill in the operator. An attempt is made to subdivide the productive operations into the most elementary tasks so that labor can be quickly trained to perform them satisfactorily. Each manufacturer is forced to train the majority of his own operators. Naturally then, the shorter the time required for this training, the sooner the results will show in the production. On the other hand, the less skill required of the operator, the more elaborate and complete the equipment must be. The amount of supervision required for both operators and equipment is also greatly increased, in both quantity and quality.

In any case, the better the training that these operators receive, the higher is the quality of the work produced. The operator should be taught to maintain the established tolerances. If the specified tolerances prove too severe in practice for economical production, they should be corrected, provided the functional requirements of the mechanism will permit. If they are not too severe, there is no excuse for violating them. The practice of adhering to the specified tolerances will do much to promote a high quality of product.

The inspection and acceptance or rejection of the components falls logically into two divisions. The first is the shop inspection which is made while the material is in process of manufacture. The object is first to test the set-up of the equipment, then by a periodic inspection of the production, to detect any changes in the set-up or defects in the equipment, and also to cull out defective work as soon as possible. The primary object here is to prevent the production of faulty parts. In the course of production, if the percentage of rejections is low and not over the normal amount, it is evidence that the requirements specified are being met, and the manufacturing facilities provided are satisfactory. If the percentage is high, it is evidence of improper conditions somewhere which should be investigated, and the trouble should be corrected at its source. Every effort should be made here to hold the product to the specified requirements.

The distinction between the testing of the manufacturing equipment and the product itself should always be kept in mind. That is, measurements made to test the accuracy of the productive equipment can be as elaborate as necessary with but little effect on the final cost of the product because such tests are required periodically. If simple methods, therefore, are not available, the more elaborate ones should be used. On the other hand, measurements that are made to test the product itself must be simple and direct to be economical.

The second division of the inspection is the final examination of the completed parts. The object of this inspection is to see that all components which will function properly are accepted, and that all unserviceable parts are rejected. This inspection is largely governed by the requirements of the components drawings, often represented by gages, and by any other specifications. It is therefore most important that these drawings give as nearly as possible the limits of parts which will function properly. Yet, as has already been noted, these drawings and specifications are incomplete at the beginning, and probably will always be so to a certain extent. Therefore a rigid adherence to the letter but not to the spirit of the drawings and specifications is unwise, as it will not aid in the acceptance of all serviceable material nor in the ultimate economy of manufacture. In addition to the written requirements, inspectors should have a certain amount of education and experience with the mechanisms involved, or with similar mechanisms, otherwise the inspection will always prove a hindrance to the main purpose.

The characteristic need for a successful inspector is a judicial mind. Since the requirements are laws, the inspection should equitably enforce them. The spirit of the requirements should be enforced in those cases where their exact expression is incomplete. If the essentials are always specified definitely and completely, it will be a fair assumption that incompletely specified conditions are relatively unimportant. Wherever possible, the requirements should be revised to make the letter and the spirit agree, but the attempt to cover every minute and unimportant detail will prove impossible in practice.

The functional requirements should be maintained in the final inspection strictly according to the specified conditions. The non-functional requirements should be handled in a more judicial manner, each case being decided on its merits. As a matter of fact, this final inspection should be in the nature of a functional inspection only. Little attention should be given here to the non-essentials other than, perhaps, a visual inspection for general quality, and some supervision of the shop inspection to see that the proper precautions are taken during the production to insure a good product. In all cases, the main effort throughout the work should be to establish, define, and maintain the essential conditions first, letting the non-essentials develop in practice. No secret, however, should be made of the fact that these non-essentials are left to work out their own salvation.

The final and complete evidence as to whether the aim has been accomplished is furnished after the mechanism has been

assembled and tested in service. If the total costs have been reasonable and the completed mechanisms assemble properly and perform satisfactorily all the required functions, it is conclusive evidence that all essentials have been mastered. On the other hand, if the costs are excessive or if the mechanism fails to assemble or to operate properly after being assembled, it is equally conclusive evidence of failure.

Discussion

O. W. Boston.[4] The cost of inspection, as reported under the various classes A, B, and C, does not vary considerably one from another. The writer wonders, however, if in class C the cost of inspection for agricultural machinery is approximately the same as that for automobiles, gasoline engines, etc. In other words, it seems that classification B covering machine tools, electric motors, turbines, etc., would more logically include automobiles, gasoline engines, etc., of class C, and leave agricultural machinery alone in class C. Agricultural machinery is, by and large, machined less and to greater tolerances than those items mentioned in class B, and it might seem, therefore, that the cost of inspection for agricultural machinery would be different from machine tools, automobiles, etc.

The writer would like, also, to ask if any information was obtained as to the relative costs of materials used in the gages, compared to the cost of material inspected; this gage material cost to include such cost of measuring instruments and gages as are used. It would seem that the ratio of costs, of material in the gages, and the material inspected would give results quite different from the ratio of labor costs. Presumably with high production-material costs the cost of inspection gages would increase. On the other hand, the ratio might show a decrease in costs of inspection gages. It would be interesting to know these figures for the job-shop method of manufacture as compared to the mass production of a given industry such as machine tools, and also to know the value of this ratio for the different classes suggested. One can well appreciate the difficulty that the author has had in securing from a questionnaire positive and reliable data.

Edwin Smith.[5] Has the author figures available to show the relation between the cost of inspection equipment and the cost of the labor involved in inspection work and also any information regarding the cost of the maintenance of inspection tools?

Author's Closure

In reply to Professor Boston, the author would call attention to the fact that machine tools, electric motors, and turbines are generally manufactured in lots of greater or lesser amounts, while automobiles, gasoline engines, and most agricultural machinery are generally carried through on a continuous production schedule. While it is true that agricultural machinery is generally machined less and to wider tolerances than the other items mentioned, the amount of inspection also becomes correspondingly reduced so that the percentage remains about the same.

In reply to the inquiries about the costs of gages, etc., the author's only information on this subject is given in the paper. In this case the initial cost of gages amounts to about $10 per employee, while the cost of their maintenance amounts to about one-tenth of 1 per cent of the factory cost of production.

Turning With Shallow Cuts at High Speeds

By H. J. FRENCH,[1] BAYONNE, N. J., and T. G. DIGGES,[2] WASHINGTON, D. C.

In this paper a method is described for testing lathe tools under shallow cuts and fine feeds. The relations are determined between the cutting speed, feed, depth of cut, and tool life for carbon and high-speed tool steels. Comparisons are made of tools of different forms and of tool life when cutting dry and with water or lard oil. Heat treatment and chemical composition of the tools are also studied, including in the case of high-speed tool steels, the effects of cobalt, nickel, molybdenum, arsenic, antimony, phosphorus, sulphur, copper, tin, aluminum, titanium, and tantalum. The results obtained under shallow cuts and fine feeds with these steels are compared with those obtained under heavy duty.

I—INTRODUCTION

MOST studies of turning have been made with relatively coarse feeds and deep cuts and it is now possible to predict, with an accuracy sufficient for many practical purposes, the cutting speeds which can be used economically in the rough turning of metals. Comparable information is not yet available for the shallow cuts used in finish turning.

The experiments described in this report relate primarily to a new method of test for lathe tools taking shallow cuts, and it was first used in a study of the effects of feed, depth, cutting liquids, and tool form upon the cutting speed to give a broad background for useful interpretation of results. The new test was then used in a study of the effect of composition and heat treatment upon the performance of carbon- and high-speed-steel tools and the results compared with those obtained in the customary rough-turning tests.

While there has recently been a tendency in machine-shop practice to replace finish turning by grinding, the discussion of a recent paper relating to the rough turning of alloy steels[3] indicated active industrial interest in test methods applicable to turning tools working at high speeds with shallow cuts and fine feeds. This is perhaps natural, since the bulk of industrial machining does not involve cutting conditions as severe as those obtaining in the usual rough-turning tests of high-speed tool steels.

II—PREVIOUS INVESTIGATIONS

It is generally believed that the methods of test developed for heavy cuts with high-speed tool steels cannot be applied successfully to the shallow cuts used in finish turning. For example, Taylor[4] cautioned investigators against using "cuts lighter than $^3/_{16}$ in. depth by $^1/_{16}$ in. feed," and stated further that "as a result of our experience we should consider practically worthless for determining laws (of cutting), all cuts that are as shallow as $^1/_{16}$ in., and we should much prefer a $^3/_{16}$-in. depth to a $^1/_8$-in. depth."

Among the reasons for these recommendations were the difficulty of maintaining constant cutting conditions with shallow cuts and the fact that when high frictional temperatures played only a minor part in the wear of the tools, as with shallow cuts, failure was not abrupt and complete, but, instead, the tools showed a gradual wearing away of the nose. This of course was reflected in a gradually changing depth of cut, and raised the question of what should be considered as tool failure. Wear of the tool nose which reduces the depth of cut by 0.001 in. is a relatively small part of the total depth usually encountered in rough turning and is of secondary importance since close adherence to dimensions is not ordinarily required. Such a change is of much greater importance in finish turning where the cuts are shallow, of the order of 0.005 to 0.010 in. or less, and where close adherence to dimensions is usually required.

The methods of test used by previous investigators for studying the gradual wear of lathe tools taking shallow cuts may be grouped under two headings: (1) direct measurements of tool wear, and (2) indirect methods of measurement.

Direct measurements of wear have been reported by Ripper and Burley[5] and Herbert.[6] In the experiments of Ripper and Burley the wear was determined by a microscope with vernier attachment. The tests, made in a lathe, were interrupted repeatedly to remove the tool from the holder and measure the wear.

Herbert's tests were made with a special tool-steel testing machine in which a tool was applied at the bottom end of a rotating tube placed in a vertical position. A heavy weight pressed the tube against a dead stop and regulated the amount of the cut. The vise in which the tool was held was mounted on knife edges and tilted as the tool wore. The tilting angle of the vise was proportional to the wear of the tool and was measured by a micrometer.

Indirect methods of measuring the wear of lathe tools have been described by Poliakoff,[7] Smith and Hey,[8] and Smith and Leigh.[9]

In the method used by Poliakoff, and also by Smith and Jinoya, the wear of the tools was determined from the corresponding increase in the diameter of the work (the bar being cut). An indicator was mounted on the tool rest immediately behind the tool and kept in continuous contact with the work. The tests were continued until the wear was greater than that selected to represent failure of the tool and the carriage moved back by hand, after stopping the test, to permit checking the changes in the depth of cut.

Smith and Hey and Smith and Leigh made use of a dynamometer for measuring the vertical forces on the tool when cutting. Tool comparisons were based on the time required for the vertical force to increase 10 per cent above its initial value. This increase was found to correspond approximately to a tool wear of 0.0015 in., and was stated to bear a distinct relation to the breakdown of the tool. In selecting the pressure on the tool as a

measure of tool life, these investigators disregarded the recommendations of Taylor and his associates who specifically stated that "no law can be established or formulated for cutting steel which expresses the relation between cutting speed and the pressure on the tool."

Some of the conclusions drawn from tests made by these different methods are compared in Table 1, which also gives a general idea of the conditions under which the tests were made. The investigators have taken different criteria for failure of the tools

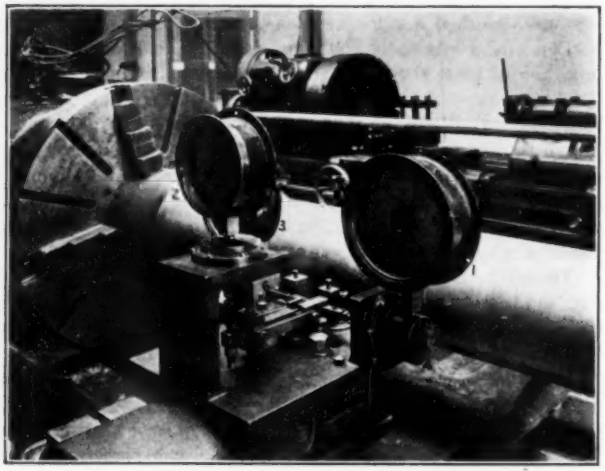

FIG. 1 DYNAMOMETER USED IN THE PRELIMINARY TOOL TESTS
(The vertical and horizontal forces are measured respectively by gage 2 and gages 1 and 3, acting through diaphragms, one of which, in its case, is indicated at 4. The diaphragms are in contact with the tool through the struts, two of which are shown at 5 and 6.)

FIG. 2 SPECIAL TOOL HOLDER USED IN THE TESTS UNDER SHALLOW CUTS AND FINE FEEDS

and have obtained what, at first glance, seem to be contradictory results. For example, Ripper and Burley found that the life of both carbon- and high-speed-steel tools, when represented by wear of 0.005 in., increased as the cutting speed decreased. Most of the other investigators referred to in Table 1 found "peaks" in the cutting speed—"tool-life" curves which showed that under some conditions increase in cutting speed resulted in an increase in the "tool life." Apparently, however, such critical speeds were found only when the working portions of the tools were kept at low temperatures by means of very shallow cuts and fine feeds, the use of cutting liquids, or both.

III—PRELIMINARY TESTS WITH A DYNAMOMETER

Tests were first made with a dynamometer with the view of correlating the changes in pressure on the tools with tool wear. The dynamometer used was similar in design and construction to that employed by Stanton and Hyde[10] and is shown in Fig. 1.

[10] T. E. Stanton and J. H. Hyde, "Forces Exerted on the Surface of Cutting Tools," Proc. Inst. M.E., 1925, part 1, p. 175.

TABLE 1 SUMMARY OF SOME OF THE RESULTS OBTAINED BY DIFFERENT METHODS OF TEST FOR LATHE TOOLS TAKING FINE CUTS

Investigator	Criterion of tool failure	Tool steel	Metal cut	Approx. range of feeds in. per rev.	Approx. range of depths in.	Coolant	Effect of cutting speed on tool life[1]	Carbon vs. high-speed tool performance	Round nose vs. broad-nose tools
Poliakoff	0.0015 in. wear (test continued to 0.002 in.)	C and high speed	0.35 C steel	0.014	0.0056	Soap and water	Life irregular with respect to cutting speed	C steel more durable than high speed	Broad nose best for C tool steel Reversed for high-speed tool steel
Smith and Jinoya	0.001 in. wear	C and high speed	Medium C steel	0.05	0.003	Soda and water	Life increases with speed	High-speed best	.....
Ripper and Burley	0.005 in. wear	C and high speed	Mild to very hard C steels	0.0275	0.020/0.120	Tested dry	For C tool steel: $V = c/A$ For high-speed steel: $V = \frac{K_1}{f^{1/2}} - (K_2 + K_3 f)d$	High speed was about ten times as good as the C steel	Tools with long cutting edges have longer life than those with short
Herbert	0.001 in. wear	C and high speed	?	0.0012 (maximum obtainable)	0.0625	Water in tube	Life irregular with respect to cutting speed	At low speeds C steel more durable than high-speed steel; at high speeds this is reversed	.....
Smith and Leigh	10 per cent increase in vertical force	C and high speed	0.35 C steel	0.0013/0.0372	0.0625 and more	Dry except in special experiments	Life irregular with light cuts; decreases continuously with speed increase for heavy cuts (0.037 feed)	At low speeds C steel as good as high-speed	.....
Smith and Hey	10 per cent increase in vertical force	High speed	0.35 C steel	0.0013	0.0625	Tested dry	Life irregular with respect to cutting speed	.....	.....

[1] V = cutting speed, f = feed, d = depth of cut, A = area of cut, and c, K_1, K_2, and K_3 are constants.

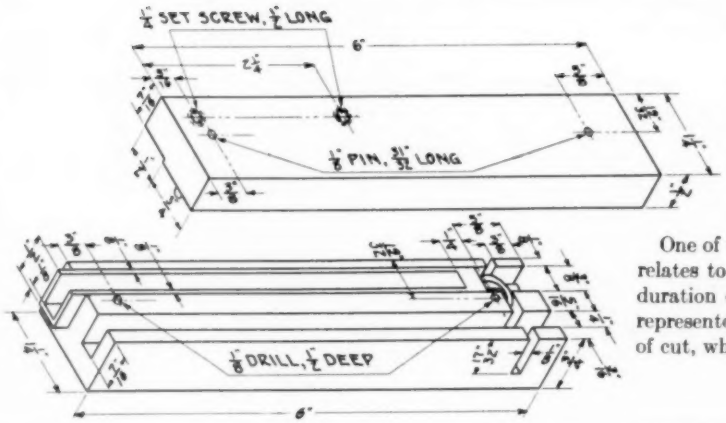

FIG. 3 SKETCH SHOWING DETAILS OF THE CONSTRUCTION OF THE SPECIAL TOOL HOLDER ILLUSTRATED IN FIG. 2

One of the disadvantages of such equipment, which was noted by earlier investigators, was the lack of rigidity of the test tools. Measurements of the diameter of the test forgings subsequent to the tool tests showed variable depths of cut from start to finish in nearly all tests. The variations were not progressive changes in one direction but appeared at irregular intervals and could be detected readily from the changes in the appearance of the cut surfaces. "Stepped cuts" were obtained in nearly all cases.

It is probable that such effects could have been minimized by refinements in the construction of the dynamometer, but since there did not seem to be any consistent relation in the preliminary tests between the vertical or horizontal forces on the tools and the tool wear, the use of the dynamometer was discontinued.

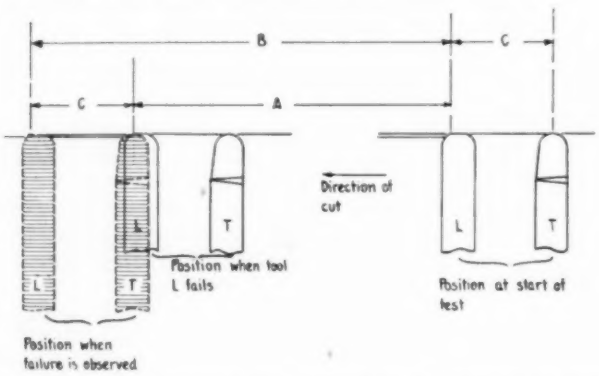

FIG. 4 DIAGRAM SHOWING CORRECTIONS TO BE APPLIED TO THE OBSERVED LENGTHS OF CUT IN THE TESTS MADE UNDER SHALLOW CUTS AND FINE FEEDS
(See text for discussion.)

IV—METHOD OF TEST USED UNDER SHALLOW CUTS

EQUIPMENT

The method of test adopted is illustrated in Fig. 2. It makes use of two tools set at equal depths in one tool holder and depends upon the fact that the "trailer" or following tool will not cut so long as the "leader" or cutting tool shows no wear.

A micrometer adjustment is provided in the groove, into which the trailer tool is placed in the tool holder as shown in Fig. 3. The leader or test tool is first clamped securely in the tool holder, which is then moved in the direction of the depth of cut until a piece of thin (cigarette) paper can just be drawn between the work and the nose of the test tool. The micrometer adjustment is then used to bring the trailer tool into a similar position, and the trailer is securely clamped in the holder by means of the setscrews shown in Fig. 3. After adjustment to equal depths, the desired depth of cut is secured by setting the carriage on the lathe in the usual manner.

One of the advantages of this method of test is its simplicity as the only special equipment required is the tool holder. Another advantage is that there is nothing to interfere with the rigidity of the test tool.

One of the disadvantages of the method is shown in Fig. 4, and relates to a correction which should be applied to the observed duration of cut. If the true length of cut of the test tool L is represented by A in Fig. 4, then B represents the observed length of cut, which differs from the true value by the amount C, repre-

[1] The recorded heat treatments were used for the lathe tools unless otherwise indicated in the text of this report.
[2] These steels were obtained from tool-steel manufacturers; all others were experimental melts.
[3] The carbon-steel tools were first normalized by air cooling from 1500 deg. fahr. for C14 and 12A; from 1575 deg. fahr. for C2; from 1675 deg. fahr. for C22. All high-speed-steel tools were first annealed, by heating for 2 to 3 hours at 1600 deg. fahr. to 1650 deg. fahr. and furnace cooling. They were preheated for 20 min. at 1600 deg. fahr. and then held 1 1/2 min. in the high-temperature furnace at the temperatures indicated.
[4] Treated by the steel manufacturer as follows: 1500 deg. fahr., 10 min.; 2375 deg. fahr., 3 min., oil quenched.
[5] Type composition; purchased under trade name.

senting approximately the distance between the two tools. This distance is small in relation to the total length of cut only when the cutting conditions permit long life. Under such conditions the correction to be applied may be neglected since it will ordinarily be within the limits of reproducibility attained in the experiments, but the reported durations of cut have all been corrected and represent A, not B, in Fig. 4. The necessary corrections of the observed lengths of cut B, Fig. 4, can readily be applied since the rate of advance of the tools is easily determined from the speed of rotation of the test forging and the feed, both of which are ordinarily recorded in any turning tests.

Except when otherwise indicated, the test tool used under shallow cuts and fine feeds had a broad nose and was of the form and dimensions shown in Fig. 5(b). A round-nose tool, of the form and dimensions used in rough turning [Fig. 5(a)], was ordinarily used for the trailer.

Procedure

From three to six tools were tested after each of two grindings for each condition investigated, and the tests were all made in sequence. For example, in the study of the effect of cutting speed on tool performance, one tool was tested at each of the selected speeds in the series, then a second tool was tested at each of the different speeds, and this procedure repeated until the desired number of tools had been tested for each condition. Only average values are used in the comparisons made throughout this report.

Testing tools in sequence has long been practiced and tends to minimize variations in results arising from inhomogeneities in the metal being cut, which is seldom entirely uniform with respect to its machining properties. While this is important in rough turning, it appears to be of even greater importance with shallow cuts. Some very large differences were encountered in the tool performance at different parts of steel forgings, which showed very uniform tensile properties at different depths and from end to end.

The chemical compositions and the heat treatments of the tools used in all of the experiments except those in which a study was made of the effects of different hardening and tempering temperatures, are summarized in Table 2. The compositions, treatments, and properties of the test forgings are given in Table 3.

How the Carbon- and High-Speed-Steel Tools Failed

With the broad-nose tools used in the experiments the leading edge first showed wear, and the crumbling or wearing away of the nose then progressed from the leading edge to the trailing edge. This shift in the working portions of the tool from the leading to trailing edges took place slowly and could be followed quite readily in the case of most of the high-speed-steel tools. It occurred more rapidly in the carbon-steel tools, which generally were ruined very soon after the leading edge showed evidence of crumbling or spalling.

In the tests with high-speed-steel tools a groove was formed on the top surface of the tool near the leading edge, and vertical grooves were also formed on the face as shown in Fig. 6. The spacing of the grooves on the face corresponded to the feeds employed in the tests and the length of the grooves was dependent upon the depth of cut. A depression or groove was also formed on the top surface of the carbon-steel tools, but there was often no evidence of the feed grooves on the face after failure. When

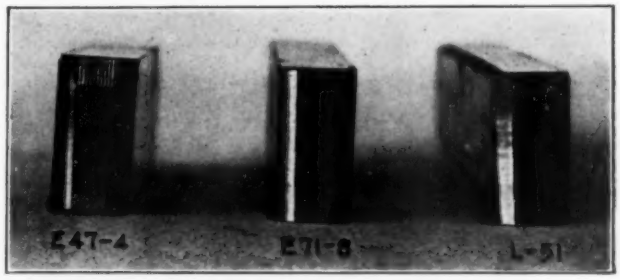

Fig. 6 New Tool and Tools Which Failed in the Tests Under Shallow Cuts and Fine Feeds

(E71-8 is a new tool. E47-4 used at 400 ft. per min. with 0.010 in. depth and 0.0115 in. per rev. feed on test forging No. 40. L51 used with 0.005 in. depth and 0.0154 in. per rev. feed at 400 ft. per min. on forging No. 40.)

visible, the feed grooves in the carbon-steel tools were not so marked as in the high-speed-steel tools.

With the method of test employed the trailer tool indicated when the leader or test tool had worn enough to produce a measurable change in the depth of cut. Experience showed that the trailer began to cut when the wear of the leader was between about 0.001 and 0.002 in., and this was considered as the point of failure of the test tools. These values apply to tests in which the two tools are originally set at equal depths, but it should be recognized that the wear representing failure may be increased by using originally a shallower setting for the trailer than for the leader. The test is therefore applicable to a wider range of conditions than those used in the experiments.

When the tools failed in a short time, it was found that wear of 0.001 or 0.002 in. was concomitant with a complete breakdown of the tool comparable to that found with deep cuts in rough turning. In other words, the nose was rubbed off to a sufficient depth to decrease the depth of cut appreciably. (See Tables 4 and 5.)

This manner of failure was characteristic of both carbon- and high-speed-steel tools, but, as already pointed out, this end point was reached at different rates in the two steels. The carbon-

[1] Tests were made on forging No. 41 with tools of the form and dimensions shown in Fig. 5(*b*).
[2] Composition and heat treatment given in Table 2.

steel tools failed almost immediately after the leading edge of the tools showed wear, whereas the high-speed-steel tools frequently continued for some time thereafter to take a full cut.

When the tools failed completely by rubbing off of the nose, a glaze was produced on the test forging just as in the rough-turning tests and gave an additional indication of failure.

When the cutting conditions permitted the tools to cut for only a short time, the selected method of test gave an end point which was concomitant with complete failure of the tool and the trailer tool became unnecessary. Under more nearly practical conditions, when the tools continued to cut for long periods, the wear on the nose of 0.001 or 0.002 in. was seldom concomitant with complete failure. Under such conditions it became impracticable to determine the time of failure without an indicator such as the trailer tool. Tests of very short duration, which might be made in the ordinary manner, even with shallow cuts and fine feeds, are of doubtful value unless it is practicable to develop at least approximate relations between such short-time tests and the long-time cutting required in practical service. Therefore a study was made of the effects of speed, feed, and depth of cut on the durations of cut.

V—EFFECT OF CUTTING SPEED ON TOOL LIFE

High-Speed-Steel Tools

The results of tests at different cutting speeds with a feed of 0.0115 in. per revolution and depths of 0.010 or 0.020 in. are summarized in Fig. 7, and show that there was a continuous increase in the life of high-speed-steel tools as the cutting speed was decreased. Within a life range of from 2 to 125 minutes the experimental results may be represented by the equation

$$V T^n = c \qquad [1]$$

in which V is the cutting speed in feet per minute, T the tool life in minutes, and n and c are constants.

In one of the two sets of tests summarized in Fig. 7, the experimental results were most closely represented by Equation [1]

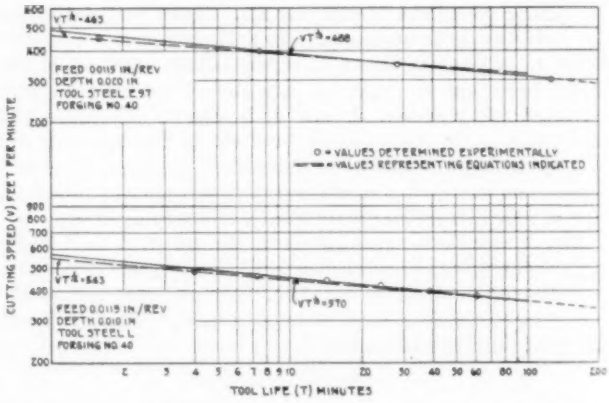

FIG. 7 RELATION BETWEEN THE CUTTING SPEED AND THE TOOL LIFE UNDER SHALLOW CUTS AND FINE FEEDS
(Tests made dry.)

when n was $^1/_{10}$, while the best representation in the second set was obtained when n was $^1/_{12}$.

When taking shallow cuts with high-speed-steel tools, Ripper and Burley[11] found that the relation between the cutting speed and tool life could be represented by Equation [1] with n equal to $^1/_{12}$. They did not report the actual values of tool life, but a study of the points plotted in their charts showed that only in some cases were the relations between cutting speed and tool life best represented by Equation [1] with $n = {}^1/_{12}$; in others, as good or better representation was obtained with $n = {}^1/_{10}$.

The value of the exponent n in Equation [1] cannot be definitely established at this time. The value $^1/_{10}$ was selected for use in this investigation since it is closer than $^1/_{12}$ to the exponent in a similar equation which Taylor demonstrated was applicable to conditions of rough turning. However, either of the quoted values should give results sufficiently accurate for practical purposes except when extrapolating to very long-time cutting from tests of relatively short duration.

Carbon-Steel Tools

The change from very short life to very long life in carbon tool steels was most often produced by decreases of less than 5 ft. per min. in the cutting speed. In the majority of the cases investigated, if the tools did not fail in less than 5 min. they continued to cut for 90 min. without sign of failure.

In general the tests were stopped after 90 min., but in a few

[11] See footnote 5.

cases tools which did not fail in this time were allowed to continue to cut for another 90 min. (total time of cutting, 3 hours) without indication of failure. This, together with the general character of the cutting-speed–tool-life curves indicated that carbon-steel tools which cut for 90 min. would, in general, cut for much longer periods such as are desired in practice.

The highest speed at which the tools would cut for 90 min. without failure was considered to represent a "critical cutting speed." It was determined by testing individual tools at successively lower cutting speeds, which differed by 2 to 5 ft. per min., until a 90-min. cut was obtained without failure.

The critical cutting speeds discussed in this report are not equal to the speeds permitting exactly 90 min. tool life, but due to the sharp increases in life with decrease in cutting speed they are so close to the latter that the two may be considered to be the same for practical purposes.

The sharp decrease in life with increase in cutting speed in the case of carbon-steel tools is probably associated with the temperatures generated at the working portions of the tools. Increase in cutting speed means increase in working temperatures, and carbon steels are known to lose hardness more rapidly with temperature rise than high-speed tool steels. The gradual change in tool life in high-speed steels is probably associated with a gradual loss in hardness with rise in temperature resulting from increase in either cutting speed, feed, or depth of cut.

VI—EFFECT OF FEED AND DEPTH OF CUT ON THE CUTTING SPEED

High-Speed-Steel Tools

A summary of the experiments with high-speed-steel tools cutting under different feeds and depths is given in Fig. 8. The relations between the cutting speed for a given tool life, the feed, and depth of cut may be represented approximately by the equation

$$V = K_1 - K_2(DF) = K_1 - K_2 A \quad \ldots\ldots [2]$$

when V is the cutting speed, D is the depth of cut, F is the feed, A is the area of cut ($=DF$), and K_1 and K_2 are constants.

With the tools and test forgings used in the experiments, as recorded in Tables 2 and 3, and a selected tool life of 90 min., Equation [2] becomes

$$V = 370 - 32\,DF \times 10^4 \quad \ldots\ldots [3]$$

For a selected tool life of 20 min. and otherwise comparable conditions, Equation [2] becomes

$$V = 430 - 38\,DF \times 10^4 \quad \ldots\ldots [4]$$

In Equations [3] and [4], V is expressed in feet per minute, D in inches, and F in inches per revolution.

Some of the plotted points are at some distance from the lines representing Equation [2] in Fig. 8, but Table 6 shows that the variations between the plotted points and the values given by Equation [2] were within ± 6 per cent. This is within the limits of reproducibility of the experiments, and is as close concordance as may be expected. As already indicated, appreciable variations were encountered in the cutting properties from point to point in the large test forgings. Likewise only minor variations from the intended depths of cut in setting the tools in the lathe represent a large percentage variation with the shallow cuts under investigation, and hence have a relatively marked effect upon the observed tool life so that reproduction of results becomes difficult.

Equation [2] indicates that the cutting speed is a function of the area of cut, and affected equally by changes in the depth and feed. This is at variance with the results of Ripper and Burley[12] for shallow cuts and those of Taylor and his associates[13] for rough turning. Ripper and Burley found that "if the area of cut is kept constant, a higher associated[14] cutting speed is obtainable when the cut is deep and the feed fine, than when the cut is shallow and the feed coarse." They expressed the relations between cutting speed, feed, and depth of cut by the following equation:

$$V = \frac{K_1}{F^{2/3}} - (K_2 - K_3 F)\,D \quad \ldots\ldots [5]$$

in which K_1, K_2, and K_3 are constants.

It is probable that the cutting speed is not affected equally by

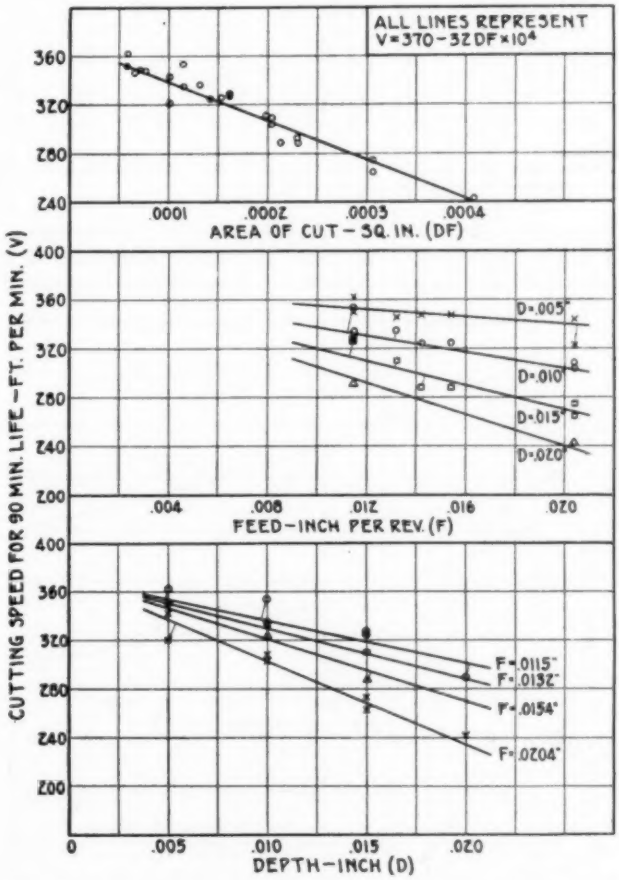

FIG. 8 EFFECT OF FEED AND DEPTH OF CUT AND THE AREA OF CUT ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS WHEN TAKING SHALLOW CUTS AT FINE FEEDS

changes in the feed and depth of cut, but it is also probable that the differences between the true laws of cutting, and the results obtained on the assumption that the cutting speed is a function of the area of cut, will be small in the case of the shallow cuts and fine feeds here investigated.

The experiments made in this investigation using different feeds and depths of cut were not carried out with a view to establishing the laws of cutting. They were made solely to permit a more general interpretation of the results of tests designed to

so long as a reasonably close concordance is obtained between the experimental results and the calculated values. In this respect Equation [2] seems adequate for present purposes and was used in the extrapolation of experimental data as required in this investigation.

CARBON-STEEL TOOLS

The effect of feed and depth of cut on the cutting speeds of carbon-steel tools is shown in Figs. 9 and 10. In this case the relations may be represented approximately by the equation

$$V = \frac{K}{DF} = \frac{K}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

With the tools and the test forgings used in the experiments and the selected tool life of 90 min., Equation [6] becomes

$$V = \frac{1.3}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where V is expressed in feet per minute and A in square inches.

Under the range of cutting conditions investigated, the cutting speeds for high-speed-steel tools were much higher than those for

carbon-steel tools, but the differences tended to diminish as the areas of cut were decreased. With sufficiently shallow cuts and fine feeds or with adequate cooling it may be possible for carbon-steel tools to have higher cutting speeds than high-speed-steel

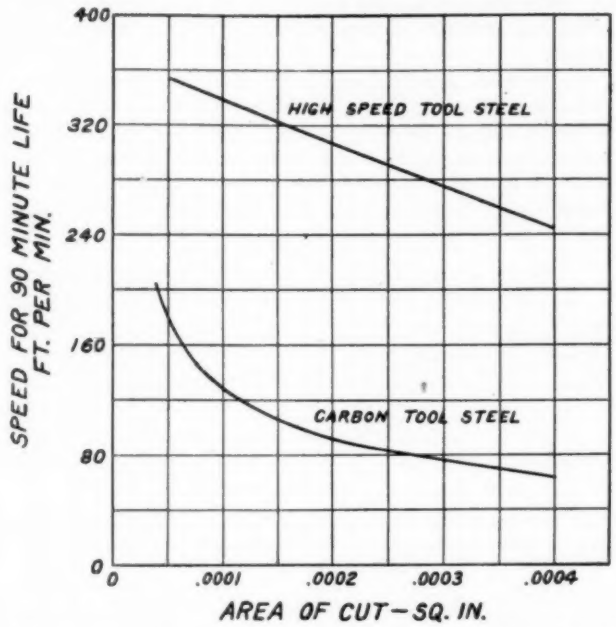

FIG. 11 COMPARISON OF THE CUTTING SPEEDS OF 1.3 PER CENT C AND THE HIGH-SPEED-STEEL TOOLS WITH DIFFERENT AREAS OF CUT
(Based on data given in Figs. 8, 9, and 10.)

tools as has been reported by some investigators.[15] This is shown graphically in Fig. 11, where the cutting speed-area of cut curve for high-speed-steel tools is a straight line and that for carbon-steel tools rises very rapidly for cuts less than about 0.0001 sq. in. The two curves may cross with sufficiently small areas of cut or if the tools are working at low temperatures through the use of cutting liquids.

VII—VARIATIONS IN TOOL FORM

SHAPE OF THE NOSE OF THE TOOL

Tests were made with tools of different forms and angles with the principal object of determining whether successful application of the described method of test was dependent upon having a broad-nose tool.

Comparisons were first made of the performance of the broad-nose tools, illustrated in Fig. 5(*b*), with tools of the forms and dimensions shown in Fig. 12. Both of the tools illustrated in Fig. 12 were similar to tools studied by the Lathe Tools Research Committee,[16] except for size, a slight increase in the front and side clearance angles and in the plan angle of the tool in Fig. 12(*a*).

The results of the tests are summarized in Table 7 and show that the tool with a plan angle of 65 deg. had a longer life (and higher cutting speed) than the broad-nose tool illustrated in Fig. 5(*b*). The sharp-pointed tool [Fig. 12(*b*)] failed immediately under the conditions of test which permitted the other two tools to cut for 20 to 35 min., but with a reduction in the cutting speed from 380 to 250 ft. per min. the sharp-pointed tools gave evidence of a measurable length of life.

The finish produced on the work appeared to be somewhat smoother and more highly polished with the broad-nose tools

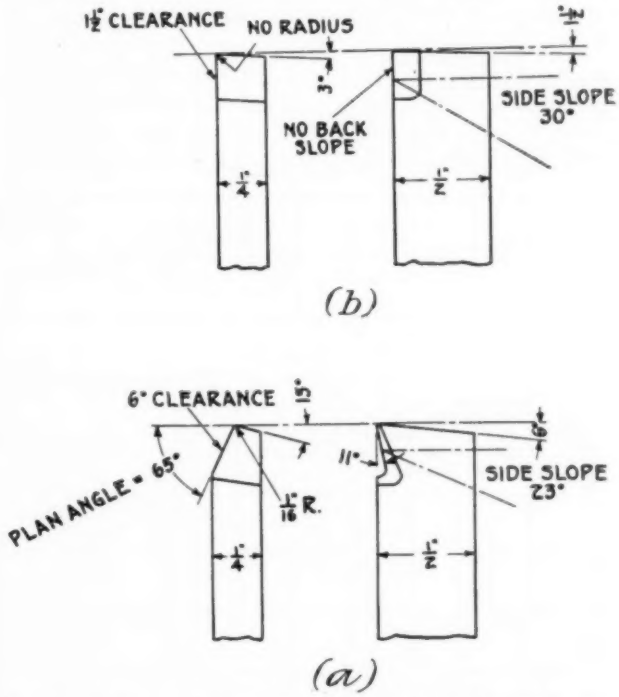

FIG. 12 TOOLS OF SPECIAL FORM USED IN SOME OF THE LATHE TESTS UNDER SHALLOW CUTS AND FINE FEEDS

[Fig. 5(*b*)] than with the tools having a 65-deg. plan angle [Fig. 12(*a*)]. The latter tools failed abruptly, whereas with the broad-nose tools, failure was progressive from leading to trailing edges, as has already been described.

Spiral chips were characteristic of the broad-nose tools, whereas straight chips and chips which were not as deeply colored were produced by the tools having the 65-deg. plan angle.

BACK SLOPE AND SIDE SLOPE IN THE BROAD-NOSE TOOLS

Further evidence that the trailer-tool method of test is applicable to a wide range of conditions is found in the results of tests made with broad-nose tools [Fig. 5(*b*)] having back slopes varying from 5 deg. to 40 deg. and side slopes of 0 deg. and 8 deg.

As shown in Fig. 13, the cutting speed of tools with 8 deg. side

[1] Composition and treatment of tool steel E97 given in Table 2. Composition and properties of test forging No. 41 given in Table 3. All tests made at 380 ft. per min. cutting speed, 0.0115 in. per rev. feed, and 0.010 in. depth, except as otherwise noted.

[2] This test made at 250 ft. per min. cutting speed.

[3] Computed by Equation [1] of the text.

slope was less than that of tools with 0 deg. side slope, and the best performance of the latter was obtained with about 30 deg. back slope. With increase to 40 deg. or decrease to 5 deg. back slope the cutting speed decreased.

In addition to showing that the broad-nose tools [Fig. 5(*b*)] had a shorter life but left a more desirable finish on the work than the tools with 65 deg. plan angle and that tool angles affected the performance of the former to an appreciable degree, these tests demonstrate that the successful application of the trailer-tool method of test is not dependent upon having tools of a particular form.

VIII—EFFECT OF LARD OIL AND WATER ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS

Since most industrial machining is done wet, the dry tests, already described, were supplemented by a few tests with water[17] or lard oil[18] as cutting liquids, but instead of making comparisons under one speed, feed, and depth of cut, tests were carried out at different speeds to give durations of cut from about 2 to 50 min.

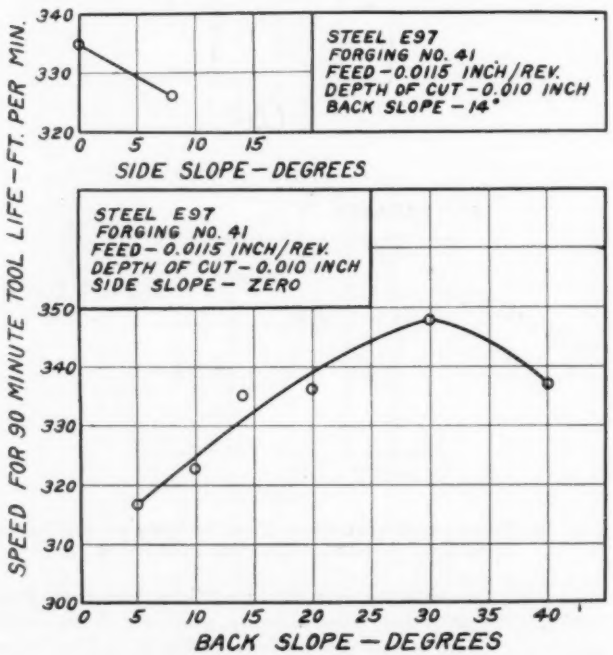

FIG. 13 EFFECT OF CHANGE IN BACK SLOPE AND IN SIDE SLOPE ON THE CUTTING SPEED OF THE BROAD-NOSE TOOLS OF FIG. 5*b* WHEN MADE OF HIGH-SPEED STEEL

A stream of the chosen liquid was thrown on the top surface of the tool through a $^1/_4$-in. nozzle at the rate of approximately 0.35 gal. per min. Alternate wet and dry tests were made to eliminate, as far as practicable, from the results variations arising from differences in the machining properties from point to point in the test forgings.

The results of the tests are summarized in Fig. 14 and show that there was a gain in the cutting speed (or tool life) from the use of either water or the lard oil. The increase was slightly greater with water than with the lard oil in tests of short duration (made with the highest cutting speeds) but equal in the tests in which tool failure occurred in about 50 min.

[17] One and one-half per cent by weight of washing soda was added to the water to minimize corrosion of the machine-tool equipment.

[18] The lard oil used was purchased under U. S. Government Master Specification No. 2d for Lubricants and Liquid Fuels. Bur. Mines Tech. Paper 323B, U. S. Department of Commerce, 1927.

In other words, the slopes of the straight lines representing the relations between cutting speed and tool life in the logarithmic plotting used in Fig. 14 were not the same for the wet and dry tests. This may be significant, although it should be noted that the differences are not much greater than the scatter of points which can ordinarily be expected with the methods of test employed.

In the tests of short duration the operating temperatures of the tools are known to have been higher than in the tests of long duration, and the gains from water, which is a more effective coolant than oils, would be expected to be greater than the gains from the lard oil. With decrease in the cutting speed the frictional temperature decreased. There was less need for cooling, and it is not unreasonable to find equal gains from the two liquids.

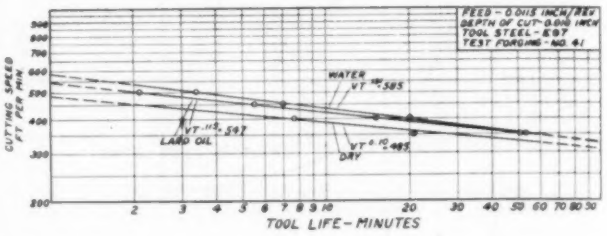

FIG. 14 RELATIONS BETWEEN THE TOOL LIFE AND THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS WHEN CUTTING WET AND DRY
(See text for discussion.)

If it is assumed that the temperatures of the working portions of the tools at given speeds, feeds, and depths of cut decreased in order from the dry tests to tests with the lard oil and water, then it may be said that the slopes of the lines representing the experimental results in Fig. 14 increase with decrease in the operating temperatures. The three conditions may then be represented in terms of Equation [1] as follows:

For dry tests:

$$VT^{0.100} = 485 \quad [8]$$

For tests with lard oil:

$$VT^{0.115} = 547 \quad [9]$$

For tests with water:

$$VT^{0.131} = 585 \quad [10]$$

If it is further assumed that the variations in the slopes of the lines in Fig. 14 were not due entirely to experimental errors but represent the true trend of effects, and that it is justifiable to extrapolate to longer cutting periods than were obtained in the experiments, then the line representing the tests with lard oil crosses that representing the tests with water. This means that a greater gain would result from lard oil than water under the long-time cutting of commercial practice.

These features are of interest, but before they can be accepted without reservations further work should be done, and as pointed out in a recent report of The American Society of Mechanical Engineers Special Research Committee on Cutting of Metals,[19] much more must be known of the true action of cutting liquids.

Possibly the greatest benefit obtained with the liquids was the better finish produced and not the increase in tool life. In general, dry turning gave a highly polished and smooth finish at the start of the cut, but there was a tendency for the surface to become less smooth as the test progressed, resulting in a very

[19] Progress Report No. 1 on "Cooling and Lubrication of Cutting Tools," Subcommittee on Cutting Fluids, Trans. A.S.M.E., vol. 51 (1929), no. 13, paper no. MSP-51-8.

poor finish on the work piece just before tool failure. At this time there was also a tendency toward chattering, and very often small shiny particles became embedded in the work piece. The finish produced when operating with the liquids was not so highly polished at the start of the cut as when dry. However, it appeared to be as smooth, and this smoothness was maintained throughout the whole cutting time.

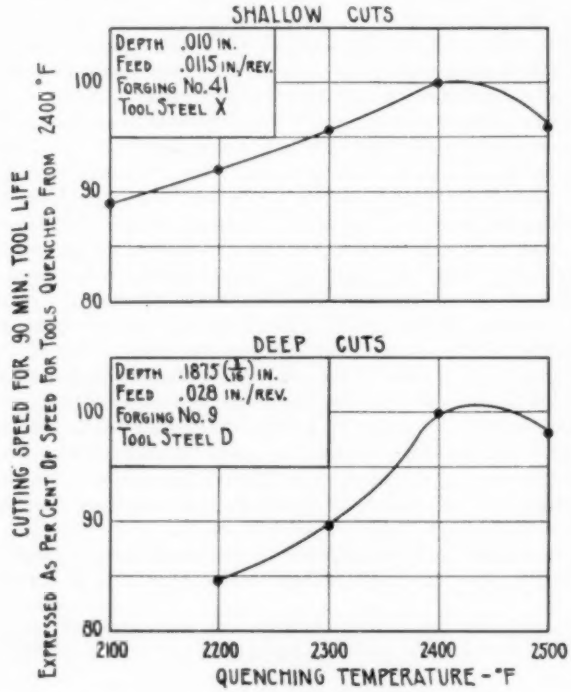

FIG. 15 EFFECT OF QUENCHING TEMPERATURE ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS UNDER SHALLOW CUTS AND UNDER HEAVY DUTY

(All tools were tempered at 1100 deg. fahr. subsequent to hardening. Compositions of the tools are given in Table 2; properties of the forgings are given in Table 3. All tests were made dry.)

IX—EFFECT OF HEAT TREATMENT OF THE TOOLS ON THE CUTTING SPEED

HIGH-SPEED-STEEL TOOLS

The performance of high-speed-steel tools is quite largely dependent upon the heat treatment to which they have been subjected, and the best results are obtained in rough turning when the customary steels containing about 0.7 per cent carbon, 18 per cent tungsten, 4 per cent chromium, and 1.1 per cent vanadium are quenched from 2400 to 2450 deg. fahr. and subsequently tempered at about 1100 deg. fahr.[20] This treatment gives close to the maximum tool life, but the tools must be well supported as they are more brittle than when hardened from lower temperatures.

Tempering at 1050 to 1100 deg. fahr. subsequent to hardening from 2400 deg. fahr. may improve the tool life slightly, but a more important effect is improved toughness.

The effect of variations in the hardening temperature upon the life of roughing tools is shown in the lower half of Fig. 15, in which the cutting speeds giving 90 min. tool life are expressed as a percentage of the cutting speed of tools quenched from 2400 deg. fahr. Fig. 15 shows that the hardening treatments which gave the best results for heavy duty also gave the best results with shallow cuts and fine feeds. However, the percentage differences in the tool performance were somewhat smaller in the case of the shallow cuts than for heavy duty.

The effects of variation in tempering temperature on tool life for both deep and shallow cuts are illustrated in Fig. 16 and show that tempering at 1100 deg. fahr. tended to improve the tool performance, particularly for shallow cuts and fine feeds. This can probably be explained by the conversion to martensite of the greater part of the austenite retained upon quenching. Under shallow cuts and fine feeds, the operating temperatures are closer to atmospheric than under conditions of rough turning where the temperatures are often close to "red heat." With shallow cuts the differences in hardness between the fully martensitic steels and those containing appreciable proportions of austenite are probably maintained throughout the life of the tools and may affect their performance. Differences in hardness probably disappear under the high temperatures reached in rough turning, due to a natural "softening" of all steels with large increases in temperature, or to the automatic conversion of the austenite to martensite by the heat generated in the test, or both.

In the foregoing experiments relative to the effects of heat treatment upon the performance of the customary high-tungsten–low-vanadium high-speed tool steel, the trailer-tool method of test for shallow cuts and fine feeds gave results similar to those obtained in the breakdown or Taylor tests for rough turning. With some compositions of high-speed steel, notably in the case of that containing nickel, the rough-turning experiments and those with shallow cuts did not necessarily place the steels in the same order of performance, as will be shown in subsequent sections of this report.

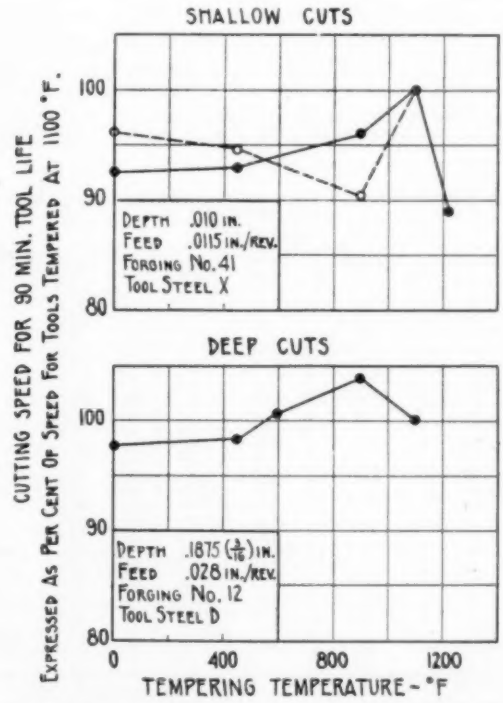

FIG. 16 EFFECT OF TEMPERING TEMPERATURE ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS UNDER SHALLOW CUTS AND UNDER HEAVY DUTY

(All tools were first oil quenched from 2400 deg. fahr. Compositions of the tools are given in Table 2; properties of the forgings are given in Table 3. All tests were made dry.)

[20] H. J. French, J. Strauss, and T. G. Digges, "Effect of Heat Treatment on Lathe-Tool Performance and Some Other Properties of High-Speed Steels," Trans. Am. Soc. Steel Treating, vol. 4 (1923), p. 353.

1.3 Per Cent Carbon-Steel Tools

Tests were made of carbon-steel tools containing 1.3 per cent carbon when quenched and tempered at different temperatures, and the results are summarized in Table 8. The cutting speed was not affected to any measurable degree by variation in the hardening temperature from 1425 to 1650 deg. fahr., nor did subsequent tempering at temperatures up to 375 deg. fahr. change the performance of the untempered tools. The toughness of the tools probably varied considerably under these different heat treatments, but this is not so important with the shallow cuts and fine feeds used in the experiments as with the deep cuts and coarse feeds encountered in rough turning with high-speed steels.

X—PERFORMANCE COMPARISONS OF DIFFERENT CARBON AND LOW-ALLOY TOOL STEELS UNDER SHALLOW CUTS

Tests were made under shallow cuts and fine feeds of carbon-steel tools containing from about 0.85 to 1.3 per cent carbon and of a low-tungsten "finishing tool steel" and a so-called non-deforming tool steel containing about 1¼ per cent manganese and small proportions of chromium and tungsten. The object of these tests was to compare the performance of the different compositions when subjected to heat treatments substantially the same as those recommended by the respective manufacturers for general purposes.

The results of the tests are summarized in Table 9 and show that the cutting speeds were nearly the same for all of the steels. The tungsten tool steel (V, Table 9) gave somewhat better performance than the manganese steel (U, Table 9) but the differences between the latter and the carbon tool steels were probably within the limits of reproducibility of the results.

The reason why the six steels tested showed comparable performance is probably to be found in the nature of the test. So long as the cutting conditions are such that the operating temperatures do not exceed certain values, which are not known at present, the tools continue to cut for long periods. With small increases in the cutting speed or other variables such as feed or depth of cut, this limiting temperature of operation is exceeded and the tools quickly fail. In other words, the test as carried out indicates the relative limits in the temperatures of operation under which the tools will stand up. Tungsten is one of the metals known to improve the resistance to "softening" of steels at high temperatures, and has probably been responsible for the slight superiority in the cutting speed of steel V, Table 9. On the other hand, the ability of steels to resist "softening" with temperature increase is probably not affected appreciably by carbon variations between 0.75 and 1.3 per cent, and the different carbon steels all showed comparable cutting speeds.

There were no detectable differences in the surfaces produced on the work piece by the different carbon- and low-alloy-steel tools.

XI—HIGH-SPEED-STEEL TOOLS OF DIFFERENT COMPOSITIONS USED UNDER SHALLOW AND DEEP CUTS

Preparation of the Steels and Tools

The chemical composition of high-speed-steel tools for rough turning was studied by Taylor and his associates[21] and has since been made the subject of many other experiments.[22–28] In fact, it is probably safe to say that continuous efforts have been made during the past twenty years to improve the performance of high-speed tool steels intended for heavy duty. Comparable studies have not been made for the shallow cuts and fine feeds which generally characterize finish-turning operations, and accordingly high-speed steels of different compositions were tested by the "trailer-tool" method described in this report and the results compared with those obtained under heavy duty. Tests were made of important industrial types of high-speed steel, such as

[21] See footnote 4.

the high-tungsten–low-vanadium steels, the low-tungsten–high-vanadium steels, and the cobalt steels. A study was also made of additions of appreciable proportions of nickel, molybdenum, titanium, and tantalum, and of the effects of elements which may be classed as impurities, such as phosphorus, sulphur, arsenic, antimony, tin, copper, and aluminum.

The chemical compositions of the steels tested are recorded in Table 2, and as there indicated the majority were experimental melts, but a few commercial steels were included for comparison.

The high-speed steels were not free from all elements other than those reported in Table 2, but, in general, only small proportions of other elements were present. In one or two cases small amounts of aluminum were added to quiet the metal in the ladle. Small proportions of nickel, cobalt, or molybdenum were probably introduced through the scrap high-speed steel which formed part of the charge in some of the heats, and other elements were probably introduced inadvertently through their presence as impurities in the ferroalloys employed.

Spectroscopic examination[29] was made of samples from many of the experimental steels, and with the exception of phosphorus, sulphur, and arsenic, which are not very sensitive in arc spectra, the results confirmed those obtained by chemical analysis as reported in Table 2. In addition to these elements small proportions of impurities were found as follows: copper, aluminum, and molybdenum were found in all the steels examined, but with the exception of the steels to which these metals were intentionally added the proportions were small and considered to be below 0.03 per cent. Small proportions of tin, introduced from the ferrotantalum, were found in the tantalum steels, E44, E45, E16, and E100. Nickel was found in samples E70, E71, E77, E51, and E87. Cobalt was found in steel E51. Nickel, cobalt, and molybdenum were present in steel E51, and if 100 per cent recovery of these elements from the high-speed-steel scrap is assumed, steel E51 contained about 0.35 per cent cobalt, 0.25 per cent nickel, and 0.10 per cent or less of molybdenum.

Steels L and E97, Table 2, used as the basis of comparisons in the study of impurities, contained traces, estimated at 0.01 to 0.03 per cent, of copper and aluminum, but there was no evidence of antimony or arsenic. The most sensitive tin lines are close to iron lines, and therefore it was difficult to get a positive indication of tin which may likewise be present in traces in these two steels.

In general, only small proportions of impurities were found by spectroscopic analysis and these should not affect the comparisons to be made, particularly as steels containing different proportions of the added elements are available in most cases to show the trends in the effects produced.

In the study of impurities, the proportions of arsenic, tin, copper, etc. were much higher in most cases than the proportions which would ordinarily be encountered in commercial high-speed steels, but it is frequently advantageous to deal with extremes so as to emphasize the effects of important variables. It should also be kept in mind that the phosphorus, sulphur, arsenic, antimony, copper, or tin were not residual but were added to the steels in the ladle, and that the effects produced may differ from those observed when the corresponding elements are carried through all stages of manufacture from the ores or introduced into the steels in other ways. Nevertheless the ladle additions made constitute a logical step in the study of the subject of impurities.

The steels produced experimentally were melted in an indirect arc furnace. The molten steel was generally tapped hot enough to permit its being held in the ladle for a few moments before casting into 55-lb. ingots having a top section about 3 in. × 3 in. and a length of 22 in. A split iron mold was used in which the ratio of mold weight to ingot weight was about 1.9; in practically all cases hot tops were used and a top discard made of about 25 per cent.

[29] Examinations made by Dr. W. F. Meggers, Chief of the Spectroscopy Section.

TABLE 10 FERROALLOYS USED IN MAKING SOME OF THE SPECIAL HIGH-SPEED TOOL STEELS

[1] As reported by the manufacturer.
[2] P = 0.057 per cent; S = 0.19 per cent.
[3] Made from California scheelite ore.

The required amounts of metallic antimony, arsenic, copper, tin, or aluminum were placed in the ladle and the molten steel poured on top. Phosphorus and sulphur were introduced into the steels by ladle additions of ferrophosphorus containing about 25 per cent phosphorus and pyrite (FeS). The titanium and tantalum were added to the metal in the furnace by placing the required amounts of their respective ferroalloys in sheet-steel containers and pushing these below the surface of the bath about 5 min. before tapping. The recovery varied but did not exceed about 50 per cent of the titanium added as carbon-free ferrotitanium of the composition shown in Table 10.

With the exception of steel E51, the steels containing titanium also contained aluminum, which was introduced by the ferroalloys used. It was largely on this account that two steels, E78 and E98, Table 2, were made with aluminum additions. Any marked effects produced by titanium could then be determined by comparison of the steels containing both titanium and aluminum with those containing only aluminum.

In one case about 97 per cent of the tantalum was recovered when using low-carbon ferrotantalum, but in general the recovery was appreciably less, varying from about 60 to 80 per cent. As will be noted from Table 10, the ferrotantalum used contained roughly 1 part of columbium for every eight parts of tantalum. While the steels made will be referred to as tantalum steels, it is to be understood that they also contain columbium. This element, if recovered in the same proportions as tantalum, is present in the steels in amounts equal to about one-ninth of the total percentages given in Table 2.

Molybdenum additions were made in the furnace with the original charge by means of ferromolybdenum of the compositions given in Table 10. However, in two cases, those of heats E107 and E109 (Table 2), the molybdenum was introduced as an impurity in the ferrotungsten (Table 10). Cobalt was added in a shot or cube form in the furnace with the original charge, while nickel was added as shot or electrolytic nickel in the furnace or in the ladle.

After casting, the ingots were allowed to become cold and were then annealed. Surface imperfections were removed on a shaper or surface grinder. Steels with heat numbers between E14 and E51, inclusive (Table 2), were forged with a steam drop hammer to $^3/_4$-in. × $1^1/_4$-in. bars; all other steels were forged to 2-in. × 2-in. bars under a press and then rolled into $1^1/_2$-in. × $1^1/_2$-in. bars. Forging and rolling temperatures were kept between about 2150 and 1800 deg. fahr. Subsequent to forging or rolling the bars were again annealed by heating 2 to 3 hours at 1600 to 1650 deg. fahr., and slowly cooling in the furnace.

Test tools about 5 in. long, with a cross-section of $^1/_2$ in. × $^1/_4$ in., were machined from the rolled or forged bars, and care was taken in grinding the nose to have the top surface of the finished tool comprised of metal adjacent to the surfaces of the hot-finished bars.

The tools were preheated for 20 min. at around 1600 deg. fahr.

introduced into the high-temperature furnace and kept there $1^1/_2$ min. and then quenched in a thin oil. These were subsequently tempered 30 to 45 min. at temperatures given in Table 2. The results described in Section IX of this report and earlier work[30] form the basis of selection of the hardening temperatures used which are recorded in Table 2. In most cases these are known to produce close to the best performance of which the several steels are capable. This does not apply to the steels containing tantalum nor to the commercial steels containing the highest

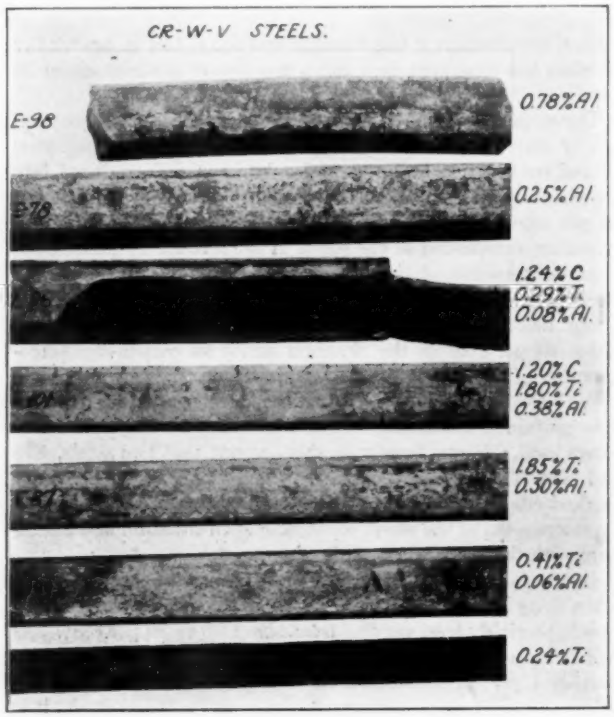

FIG. 17 APPEARANCE OF SOME OF THE ROLLED OR FORGED HIGH-SPEED-STEEL BARS CONTAINING TITANIUM AND ALUMINUM
(See Table 2 for detailed chemical composition.)

proportions of cobalt, which, in individual cases were treated by, or according to the recommendations of, the manufacturer.

HOT-WORKING AND MACHINING PROPERTIES

An adequate idea of the working and machining characteristics of the steels listed in Table 2 can probably be obtained only under conditions approaching those of commercial production, but certain definite effects were observed in the working and machining of the experimental melts which deserve mention at this time.

Difficulties were encountered in forging two of the molybdenum steels, E31 and E29, Table 2. In both heats the ingots cracked badly and only small proportions were secured in final bar form. The tungsten-molybdenum steel (E31) was perhaps the worst in this respect as the ingot split under the first few light blows of the hammer. Possibly modifications in the forging practice employed would have been productive of better results, but it appeared that these molybdenum steels were more sensitive to working conditions than the ordinary types of high-speed steel.

So-called "sweating out" of the molybdenum—visible by the thick, bluish smoke arising from the steel—was observed only during forging (not in heat treatment), but examination of the forged bars of steel E29 indicated negligible losses of molybdenum.

[30] See footnote 20.

TABLE 11 MOLYBDENUM FOUND IN SUCCESSIVE LAYERS BENEATH THE SURFACE OF FORGED BARS OF STEEL E29[1]

Location of sample with respect to pickled and brushed surface	Molybdenum, per cent
Entire cross-section of bar	7.18
0 to 0.003 in. below surface	7.06
0.003 to 0.006 in. below surface	7.14
0.006 to 0.009 in. below surface	7.19
0.009 to 0.012 in. below surface	7.15
0.012 to 0.015 in. below surface	7.16
0.015 to 0.018 in. below surface	7.16

[1] Chemical composition given in Table 2.

Quite probably the smoke observed in forging was the volatilization of the molybdenum oxide already forming part of the scale.

One of the forged and annealed bars was first pickled in an ammoniacal citrate solution to loosen the scale, which was then carefully brushed or chipped from the underlying metal. Six successive cuts, each 0.003 in. deep, were then taken beneath the cleaned surface, and each of the six samples analyzed for molybdenum. Table 11 indicates negligible losses of molybdenum in the unoxidized metal unless the losses were concentrated in very shallow outer layers. However, this seems improbable, since, as pointed out by Bain,[31] molybdenum volatilizes very slowly, even in vacuo, and diffuses slowly in iron alloys, whereas the oxide of molybdenum is quite volatile. Rapid diffusion and rapid

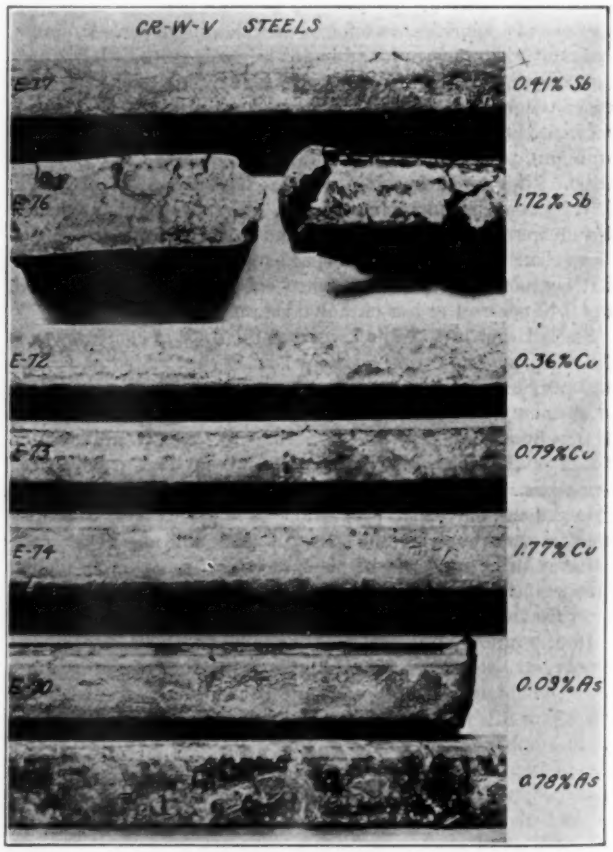

FIG. 18 APPEARANCE OF THE ROLLED HIGH-SPEED-STEEL BARS CONTAINING ARSENIC, ANTIMONY, OR COPPER
(See Table 2 for detailed chemical composition.)

volatilization would both be necessary for appreciable losses of metallic molybdenum at the unoxidized surfaces of the steel.

The steel containing 0.78 per cent aluminum did not have as good hot-working properties as steels without appreciable proportions of this element; see bad corner cracks (Fig. 17).

[31] E. C. Bain in discussion of paper referred to in footnote 27.

One of the steels containing titanium (E96) showed a high degree of hot shortness in rolling, although it seemed to forge in a satisfactory manner. This was probably not due either to the aluminum (0.08 per cent) or to high carbon (1.24 per cent) since a steel with equal carbon (E101) and steels with higher proportions of aluminum (0.38 per cent aluminum in steel E101 and 0.30 per cent aluminum in steel E87) had more satisfactory working properties. The splitting of the forged bar in rolling as shown in Fig. 17 may have been due to segregation. In this connection it should be noted that in this steel the recovery of titanium was only about 15 per cent of that added to the molten metal.

In general, the difficulties in hot working the different steels were more pronounced in rolling than in forging or pressing. The steels containing 1.7 per cent antimony or 1.8 per cent tin showed a high degree of hot shortness and could not be forged or rolled (see Fig. 18). The ingot of steel E48 containing 1.2 per cent tin "smoked" in forging like the high-molybdenum steels.

None of the other steels gave appreciable difficulties in forging, but several showed surface cracks, mostly at the corners, on rolling. Among these were the steels containing 0.4 per cent antimony, the steels with around 0.8 per cent or more of copper, the steel containing 0.8 per cent arsenic, and the steel containing 1.4 per cent carbon and 1.10 per cent tantalum.

All of the high-speed steels referred to in Table 2 could themselves be readily machined when in the annealed condition except the steel containing 1.8 per cent copper and the three steels containing about 3¾ per cent nickel and 0.6 to 0.7 per cent carbon. The steel with copper (E74) was machined with difficulty, but it was impossible to machine two of the nickel steels, E22 and E14, either in the cast or forged conditions even after prolonged annealing. Steel E130 was machined with difficulty, but with comparable proportions of nickel and lowered carbon content the machining properties were greatly improved. Steel E41, containing about 0.5 per cent carbon and 3½ per cent nickel, while not "soft," could be machined without great difficulty after annealing.

General Comments on the Lathe Tests

The steels referred to in Table 2 and the lathe-tool tests to be discussed were made at intervals over a long period of time on different test forgings, so that a direct comparison of all the tools is not practicable. This does not prevent determination of the effects of the added metals considered since each set of tests was considered to be complete in itself, and included one or more of the plain chromium-tungsten–vanadium high-speed steels as the basis for comparisons.

All tests were made at selected speeds, feeds, and depths of cut and the tool life determined. From six to twelve tools of each steel were tested for each of the selected cutting conditions. However, instead of reporting the average tool life, comparisons are made of the cutting speed permitting a tool life of 90 min. This was obtained from the average tool life by means of Equation [1] with $n = 1/10$ for tests made under shallow cuts and fine feeds ("trailer tool" tests) and with $n = 1/7$ for tests made with heavy cuts and coarse feeds (rough turning).[32]

The chromium-tungsten–vanadium steels used as the basis of comparisons in a majority of cases were experimental melts made in the same manner as the steels containing additions of the special elements. However, in some cases commercial high-speed steels were substituted for the experimental steels so that the performance of the different lathe tools might be viewed in the light of commercial products. The results recorded in Table 12 show that the experimental steels gave comparable performance to the commercial steels of like composition which were selected for comparisons under either shallow cuts and fine feeds or deep cuts and coarse feeds.

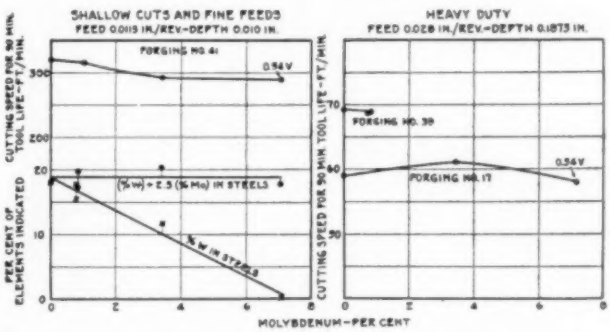

FIG. 19 EFFECT OF MOLYBDENUM ON THE CUTTING SPEED OF CHROMIUM-TUNGSTEN–VANADIUM-STEEL TOOLS WHEN TAKING SHALLOW CUTS AND WHEN TESTED UNDER HEAVY DUTY

(The molybdenum in these steels replaced a part or all of the tungsten, as indicated graphically on the left side of the chart and as explained in the text. Compositions of the tools and their heat treatment are given in Table 2; properties of the forgings are given in Table 3. All tests were made dry.)

Steels With Molybdenum

Many of the cobalt high-speed steels contain from 0.5 to 1 per cent of molybdenum, but ferrotungsten containing appreciable proportions of molybdenum has not always been considered to be desirable by American steel manufacturers.[33]

The four steels containing molybdenum (Table 2) may be said to fall into two classes, the one in which molybdenum was introduced as an impurity in the ferrotungsten, made from California scheelite ores, and the second in which molybdenum was used intentionally as a replacement of part or all of the tungsten.

Steels E109 and E107 were made with the idea of determining whether small amounts of molybdenum produced any appreciable effects upon the tool performance of the customary chromium-tungsten–vanadium high-speed steels. In steels E31 and E29 part or all of the tungsten was replaced by molybdenum in the

[32] The basis of the selected values for the exponent n in Equation [1] is discussed in Section V of this report and also in the reference of footnote 3.

0.76	2.82	12.12	1.28	2.06	17.27	..	96	
0.75	2.79	...	1.29	5.79	14.47	..	112	

approximate ratio of 1 part molybdenum for each 2½ parts of tungsten. This ratio represents approximately equivalent effects as determined in lathe-tool tests by Arnold and Ibbotson.[24]

While not strictly accurate, all four of the steels with molybdenum may be considered to be modifications of the customary high-tungsten–low-vanadium high-speed steel in which 1 part of molybdenum has replaced approximately 2½ parts of tungsten, and it is on this basis that the results of the lathe tests are summarized in Fig. 19.

It would appear from Fig. 19 that molybdenum may be substituted for part or all of the tungsten without radically changing the lathe-tool performance under shallow cuts and fine feeds or under heavy duty. If the results in Fig. 19 show any definite trends, they are that molybdenum is somewhat disadvantageous from the standpoint of shallow cuts but may improve the steels for heavy duty.

More definite conclusions cannot be drawn since steels E31 and E29 are respectively low in carbon and in vanadium, and the importance of these variations when taking shallow cuts is not known at this time.

The performance of the molybdenum steel E29 (without tungsten) was somewhat irregular under shallow cuts, as is shown in Table 13. The cutting speed in one set of tests was almost identical with that of the tungsten steel E97, but in another set of tests made with a deeper cut was somewhat lower.

The rough-turning tests did not establish superiority or inferiority of the high-speed-steel tools containing molybdenum, and in this respect the results in Fig. 19 are consistent with those obtained by earlier investigators who, in some cases, found that the steels with molybdenum gave better performance than the tungsten steels while in other cases this order was reversed. Detailed comparisons of the results of some previous investigations are given in Table 14.

As far as can be judged from the described tests, the replacement of tungsten by molybdenum is not a substitution which should be advocated for lathe tools, but in case of a depleted tungsten supply molybdenum would be very useful in producing steels with at least the same general order of performance as is obtained with the present tungsten high-speed steels.

The high-molybdenum steels such as E29 have one advantage over the tungsten steels for roughing tools in that their hardness

[24] J. O. Arnold and F. Ibbotson, "The Molecular Constituents of High-Speed Tool Steels and Their Correlations With Lathe Efficiencies," *Jl. Iron & Steel Inst.*, vol. 99 (1919), no. 1, p. 407.

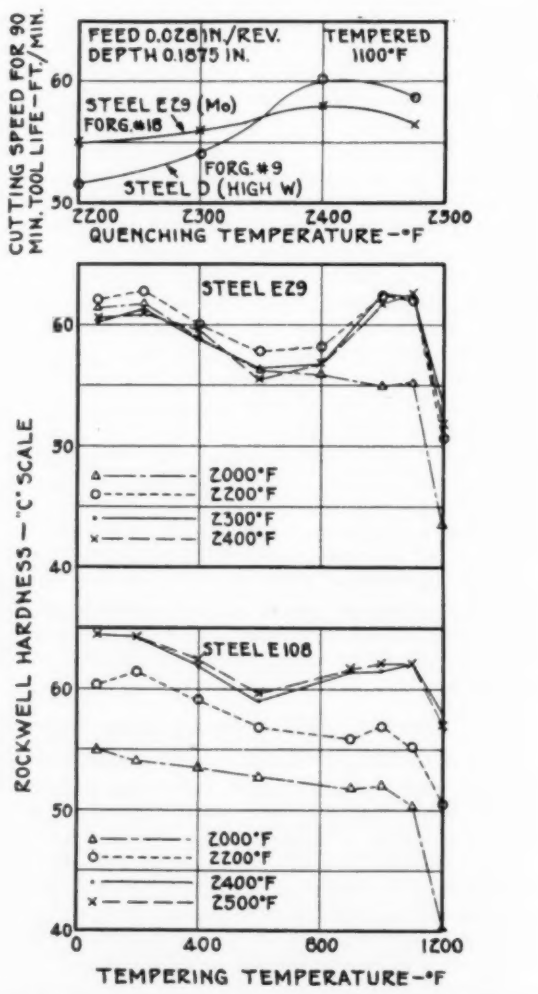

FIG. 20 EFFECT OF HEAT TREATMENT ON THE CUTTING SPEED AND HARDNESS OF SOME OF THE HIGH-SPEED STEELS CONTAINING MOLYBDENUM

(Composition of the tools and their heat treatments are given in Table 2; properties of the forgings are given in Table 3. All lathe tests were made dry. Quenching temperatures are shown in the body of the chart. The cutting speed of steel D containing no molybdenum is given for comparison with the molybdenum steel E29.)

and performance is not so largely affected by variations in the hardening temperatures as is shown in Fig. 20. When hardened from low temperatures around 2200 deg. fahr., the high-molybdenum steel actually showed better performance than the customary tungsten steels similarly treated. On the other hand, the hardness of the tungsten steels containing 1 per cent or less of molybdenum was the same as that of corresponding steels without molybdenum when subjected to the same heat treatments.

Up to the present time it has not been practicable to expect uniformly good performance from high-molybdenum high-speed-

steel tools, but more extended experience with such steels would probably result in the development of a technique in manufacture and handling which would result in a more satisfactorily uniform performance.

Steels With Cobalt

Cobalt has been an important element in the so-called tungsten-less alloys for high-speed cutting tools, but the steels considered here are the customary chromium-tungsten-vanadium steels modified only by additions of cobalt. In the commercial steels of this type, from 2.5 to 5 per cent of cobalt has usually been added, but more recently steels with much higher proportions of cobalt have been placed on the American market. Some of these also contain molybdenum in proportions up to about 1 per cent, but since the results already described showed that 1 per cent or less of molybdenum had no appreciable influence on the cutting speeds of the customary chromium-tungsten-vanadium steels, either with shallow cuts or under heavy duty, the presence of 0.6 and 0.9 per cent molybdenum, in steels CC and Y, respectively, Table 2, may be disregarded.

Several advantages are known to result from the addition of cobalt to the customary high-speed-steel compositions. Steels with around 5 per cent cobalt can be hardened from somewhat higher temperatures than would be safe for the corresponding steels without cobalt,[35,36] and under such conditions of treatment will, on the average, give better performance under very heavy duty where the deep cuts and coarse feeds produce high frictional temperatures.

Another advantage of the cobalt steels reported by European investigators[37] is that their performance is not so largely dependent upon the hardening temperature as is the case in corresponding steels without cobalt, and with low hardening temperatures, say, around 2300 deg. fahr., higher hardness and better performance can be expected. However, the cobalt steels are reported to acquire a soft skin on hardening,[38] with the result that they have not been widely used in form cutters or other tools which must be heat treated in finished form.

The high-cobalt steels, similar to CC and Y, Table 2, have been reported to give excellent performance in cutting hard metals; it is claimed[39] they have also made practicable the commercial machining of 14 per cent manganese steels, but the best performance is obtained only when the highest possible hardening temperatures are used.

Under shallow cuts and fine feeds, higher cutting speeds were shown by the steels with cobalt than by those without, but 8 to 12 per cent of cobalt was no more effective than 5 per cent (Fig. 21). Furthermore, the benefits derived from the cobalt were not large, amounting to 10 to 25 ft. per min. for cutting speeds of the order of 325 ft. per min.

Similar effects were found in the heavy-duty tests as is shown in Fig. 21. With the exception of steel CC, Table 2, the cutting speed increased with the proportion of cobalt, but the increase between 3.5 and 12 per cent was not nearly as large as that between 0 and 3.5 per cent. With 3.5 per cent cobalt there was a somewhat larger percentage gain in the heavy-duty tests than in the tests under shallow cuts and fine feeds.

Superior performance of the steel with 3.5 per cent cobalt was probably due to the fact that it was hardened from a temperature 50 to 75 deg. fahr. higher than that used in hardening the 8 per cent and 12 per cent cobalt steels and the steel without cobalt. Results reported by Oertel and Polzguter,[40] which have been included in Fig. 21, indicate that cobalt additions around 3 per cent do not result in greatly increased cutting speeds when the steels are all hardened from the same temperatures.

There is little doubt that cobalt by itself tends to increase the cutting speed, but the maximum benefits are derived only with modified heat treatments. The results given in Fig. 21 show further that cobalt additions are of somewhat greater benefit for heavy duty than for tools used with shallow cuts and fine feeds. But in rough-turning nickel steels such as were used in the described experiments, increase in cobalt above about 5 per cent did not produce improvements commensurate with those resulting from additions of 3.5 to 5 per cent cobalt and high hardening temperatures.

Steels With Arsenic, Antimony, Copper, or Tin

As a general rule, little attention is paid by consumers to the presence of copper, tin, arsenic, or antimony in commercial high-speed tool steels, although it is known that all of these elements

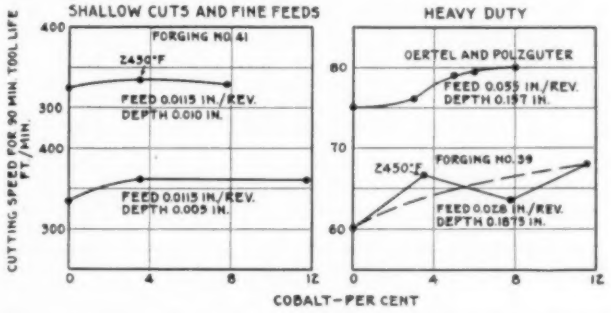

Fig. 21 Effect of Cobalt on the Cutting Speed of High-Speed-Steel Tools When Taking Shallow Cuts and Under Heavy Duty

(Compositions of the tools are given in Table 2; properties of the forgings are given in Table 3. Unless otherwise indicated the tools were oil quenched from 2375 to 2400 deg. fahr. and tempered at 1050 to 1100 deg. fahr. All tests were made dry. The source of the data credited to Oertel and Polzguter is given in footnote 24 of the text.)

will be found occasionally, and some of them frequently, in the American products. Some may be introduced from scrap which forms part of the original charge, or, as is sometimes the case with tin and arsenic, small proportions may be present as impurities in the ferroalloys used in manufacture. In any case, arsenic, antimony, copper, and tin are generally believed to exert harmful effects upon high-speed tool steels.

According to Sandberg,[41] copper, tin, arsenic, bismuth, and antimony are ordinarily present in small amounts in high-speed steels, but have no ill effects unless they are present, individually, in excess of 0.02 per cent. McKenna[42] states that the detrimental effects of tin, copper, and arsenic are not generally realized by the trade, and that small quantities of these impurities are exceedingly harmful. The character of the data upon which these statements are based is not known, and technical literature does not contain information on the magnitude of the effects produced by different proportions of the metals in question or whether they are equally deleterious for all classes of service. The need for further information is shown by inquiries which have been received by the Bureau from time to time from consumers and producers and by the fact that the American Society

for Testing Materials has a committee appointed to study the effects of tin and arsenic in high-speed tool steels.

A large part of the results here described were discussed in a preliminary report,[42] but since a much broader background is now available for the interpretation of the tool tests under shallow cuts and fine feeds, reference will again be made briefly to the effects of copper, tin, arsenic, and antimony upon the performance of high-speed-steel turning tools.

The results of tests under shallow cuts and fine feeds and also those under heavy duty are grouped in Fig. 22, and show that the influence of the different elements considered was a function of the conditions to which the tools were subjected.

With shallow cuts, each of the four elements, copper, tin, arsenic, and antimony, adversely affected the tool performance, and in each case the magnitude of the decrease in tool life or the

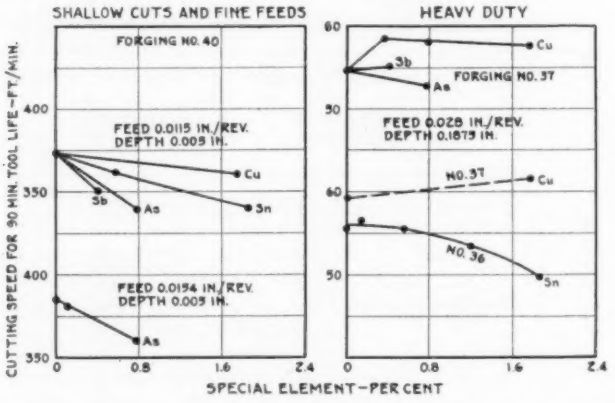

FIG. 22 EFFECTS OF ARSENIC, ANTIMONY, COPPER, AND TIN ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS UNDER SHALLOW CUTS AND UNDER HEAVY DUTY

(Compositions of the tools and their heat treatment are given in Table 2; properties of the forgings are given in Table 3. All tests were made dry.)

cutting speed became greater as the proportion of the impurity was increased. Copper was the least harmful; next in order came tin, while arsenic and antimony were the most objectionable.

The effects of the several elements upon the performance of roughing tools did not necessarily correspond to those observed with shallow cuts. The arsenic addition lowered the cutting speed, but the addition of 0.4 per cent antimony or 0.5 per cent or less of tin had no measurable effect. Higher proportions of tin lowered the cutting speeds, but the high-speed steels containing copper showed slightly better performance than the corresponding steels without copper. This effect was confirmed in two independent sets of tests as is shown in Fig. 22.

The described results seem to justify the conclusions that copper has the least harmful effect of the four metals here considered upon the cutting speeds of high-speed-steel turning tools; and that small proportions of tin, below about 0.1 per cent, do not seriously affect the cutting speeds, but that arsenic and antimony should be kept out of high-speed tool steels to be used under varied conditions of service.

In general, the presence of small proportions of these different elements is much less important for tools to be used only in rough turning than when shallow cuts are considered. This is perhaps to be expected, since any tendency to promote crumbling of the cutting edge, which would be observed with shallow cuts when the frictional temperatures are low, would probably be masked by the softening of the steel at the high operating temperatures encountered in rough turning.

[42] H. J. French and T. G. Digges, "Effects of Antimony, Arsenic, Copper, and Tin in High-Speed Tool Steel," Trans. Am. Soc. Steel Treating, vol. 13 (1928), p. 919.

In addition to lathe-tool tests, Rockwell hardness tests were made on samples quenched and tempered in various ways, and with few exceptions the hardness of the steels containing the different impurities was practically the same as that of the steels without these impurities similarly treated. The addition of 0.15 per cent tin increased the hardness of the steel as oil quenched from 2000 deg. fahr.; when the proportion of tin was raised to 0.57 per cent, there was an additional increase in the hardness, but with further increase in tin the hardness decreased slightly.

The additions of antimony, arsenic, copper, or tin produced no outstanding changes in the structures of the high-speed-steel tools, although there was a tendency for increase in grain size with increase in copper content and a decrease in grain size as the proportions of antimony, arsenic, or tin were increased. Typical structures are shown in a preliminary report referred to in footnote 43 of the text.

STEELS WITH ALUMINUM

The principal reason for considering the effects of aluminum upon the high-speed-steel tools was the presence of this element in the ferrotitanium available and its consequent introduction into the steels containing titanium. Without knowing something of the magnitude of the effects of the aluminum, the trend of the effects produced by the titanium could not be established. However, aluminum is widely used as a corrective agent in steel-making practice. While ordinarily avoided in the manufacture of high-speed tool steels, aluminum is sometimes added in the ladles or molds and its influence upon the performance of high-speed-steel cutting tools becomes important.

As far as is known, the effect of aluminum upon high-speed-steel tools has not been made the subject of investigations which have reached the stage of publication, but generally useful information has been gathered in other fields. Small additions of aluminum to molten iron alloys will react with any iron oxide present to form alumina, a part of which may be eliminated under suitable conditions. With larger additions of aluminum the same reactions can take place, but the larger part of the aluminum is dissolved in the steel as aluminum.

According to Guillet,[44] the presence of aluminum in iron-carbon alloys "has the effect of preventing the pearlite from assuming its ordinary forms; it is, in a manner, contorted, and forms little nodules which are the more easily colored by picric acid, and the more closely resemble troostite, in proportion as the percentage of aluminum increases. With a very high percentage of aluminum it is even possible to have free cementite formed in a hypo-eutectoid steel.

"Quenching transforms only the nodules of the preexisting pearlite, giving place to martensite, generally encircled around its edges by troostite. The result is always the same, no matter what the temperature of quenching. It must therefore be recognized that the iron-aluminum solution is incapable of dissolving carbon.

"From the mechanical point of view quenching has no effect except when the pearlite exhibits its ordinary structure, that is to say, so long as the aluminum is below 3 per cent."

Aluminum was found to increase the tensile strength and decrease the elongation and reduction of area, slowly at first but rapidly when the aluminum was raised above 3 or 4 per cent; the brittleness also increased rapidly.

The effects produced in the high-speed steels by aluminum were similar in some respects to those described by Guillet for carbon steels, but were observed with smaller additions of aluminum. As is shown in Figs. 23 and 24, the hardness of the steels containing aluminum decreased, after either quenching or

[44] L. Guillet, "Quaternary Steels," *Jl. Iron & Steel Inst.*, 1906, no. 2, p. 1.

quenching followed by tempering, as the proportion of aluminum was raised from practically zero to 0.8 per cent. However, the numerical values of the hardness obtained were quite largely dependent upon the quenching temperature. In effect, the entire set of hardness curves (Fig. 23) was shifted to lower values of hardness as the proportion of aluminum was increased.

Aluminum also adversely affected the performance of the high-speed-steel tools both with shallow cuts and under heavy duty as is shown in Fig. 25. In fact, aluminum was one of the few metals considered which in small proportions (around 0.3 per cent) produced a measurable decrease in the cutting speeds in rough turning. This decrease became greater as the proportions of the aluminum were increased, and with 0.8 per cent the drop in the cutting speed was greater than that produced by equal proportions of any of the other elements considered.

Deleterious effects were observed with shallow cuts and fine feeds, but in this case the effects of the aluminum were about on a par with those of arsenic and antimony, and more marked than those of either tin or copper.

The reasons for decrease in the hardness and the tool performance with increase in the aluminum have not been established, but the structures of the steels throw some light on this subject.

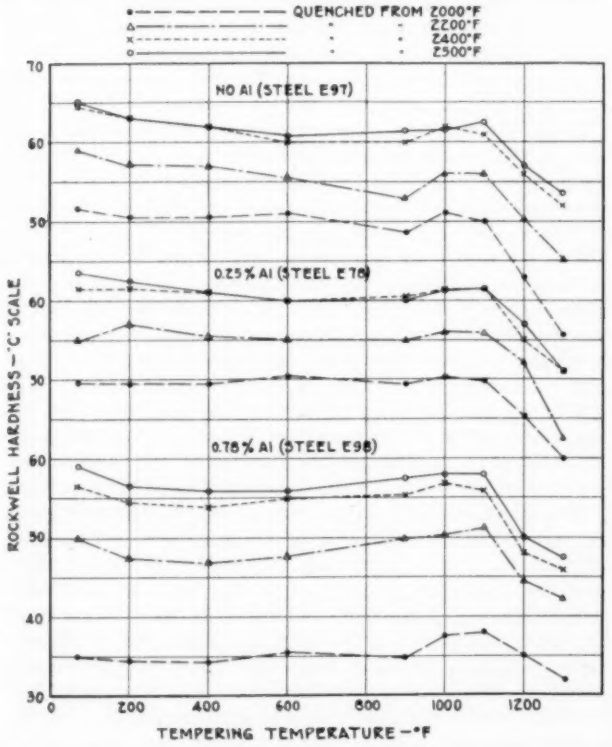

FIG. 23 HARDNESS OF HIGH-SPEED STEELS CONTAINING DIFFERENT PROPORTIONS OF ALUMINUM WHEN SUBJECTED TO DIFFERENT HEAT TREATMENTS
(Compositions of the steels are given in Table 2.)

The structure of one of the quenched and untempered high-speed-steel tools containing about 0.8 per cent aluminum was perhaps the most illuminating since it showed characteristics somewhat similar to those described by Guillet for carbon steels. As is shown in Fig. 26(*c*), a large number of undissolved particles were found at the austenite grain boundaries and the outer areas of the zones of concentration of these undissolved constituents were encircled by more darkly etched areas perhaps representing a structure comparable to troostite.

Such a large number of undissolved aggregates are not ordinarily found in the customary high-speed steels quenched from comparable temperatures [Fig. 26(*a*)] and probably represent a decreased dissolving power of the austenite (matrix) for one or more of the elements, carbon, chromium, tungsten, and vanadium

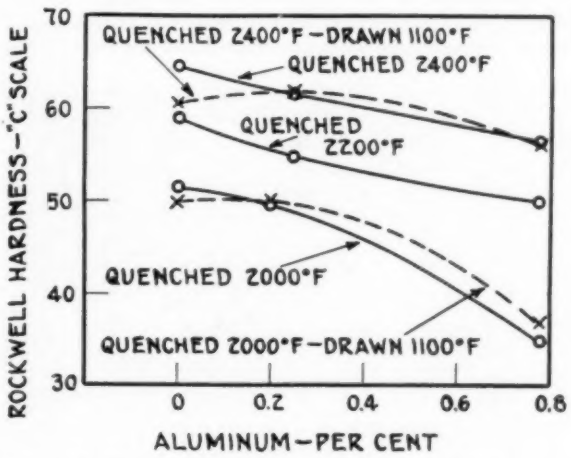

FIG. 24 EFFECT OF ALUMINUM ON THE HARDNESS OF QUENCHED AND TEMPERED HIGH-SPEED STEEL

which constitute the key elements in the steels under consideration.

In other words, the 0.8 per cent aluminum has decreased the solubility in the austenite of one or more of the elements mentioned, and through the resultant precipitation has lowered the hardness and other useful properties of the steel. Along with this precipitation is evidence of the formation of low-melting-point eutectics [see arrow, Fig. 26(*c*)] which are only evident in the customary high-speed steels as cast or when overheated. Such partial melting is an added source of danger in high-speed-steel tools, and probably contributed in a measurable degree to the poor performance described.

The exact nature of the compounds and the low-melting eutectics has not been determined, but the observed structures, hardness, tool performance, and poor hot-working properties previously described clearly show the importance of guarding against the introduction of more than very small proportions of aluminum in high-speed tool steels.

STEELS WITH TITANIUM

So far titanium has not shown much promise as an alloying element in steels and is now mainly used as one of a number of corrective agents (scavengers) in steel making, and in this latter

field it seems to combine most readily with oxygen and nitrogen. The present situation regarding the applications and effects of titanium in steels is about as described by Gillett and Mack[45] as follows:

"The alloying effect of titanium seems to be negligible, its only use being as a scavenger to remove oxygen and perhaps nitrogen. It seems to reduce segregation of carbon and of impurities. Some

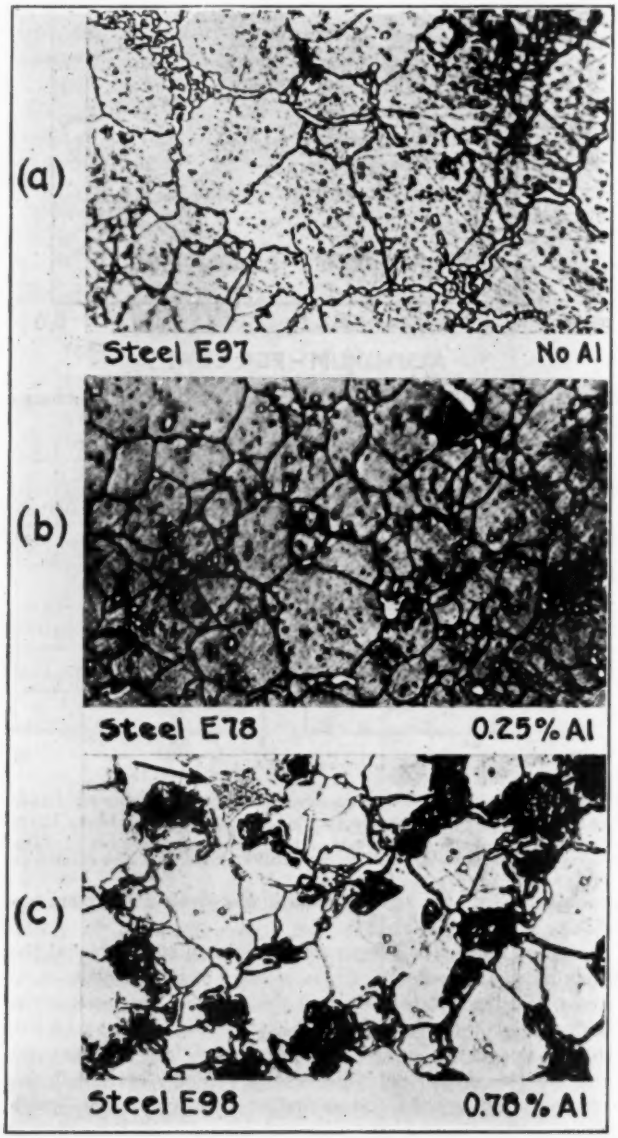

FIG. 26 STRUCTURES OF HARDENED HIGH-SPEED STEELS CONTAINING DIFFERENT PROPORTIONS OF ALUMINUM ×750
(Samples oil quenched from 2350 deg. fahr., not tempered. Etched with 2 per cent HNO_3 in alcohol.)

of the data cited by the advocates of titanium[46,47] to show its value as a scavenger lie well within the range of results obtained without it and the proof of its usefulness is seldom clear-cut.

A thorough study[48] of the deoxidation of rail steel by titanium and by silicon has been made by the Bureau of Standards. This shows that the action of titanium in restraining segregation is definitely shown only in the top of the ingot, that the average mechanical properties of the steel are not noticeably altered by titanium, and that the claim that the oxidation products of titanium do not remain in the steel is not in accord with the facts.

"Stoughton[49] believes that titanium causes occluded oxidized materials which would cause inclusions to be more readily separated from the melt, and Giolitti[50] mentions the use of titanium and vanadium as having specific action in developing fine grain on heat treatment. Titanium probably serves a useful purpose as a scavenger, but it has no place in a list of true alloying elements."

According to recent studies by Tamaru,[51] titanium up to 4 per cent is in solid solution in the ferrite of carbon steels; it lowers the solubility of carbon in the austenite and accelerates graphitization. As the titanium in the steel was increased the carbon content of the eutectic decreased.

True alloying of any appreciable amounts of titanium in steels is not readily accomplished. Ferrocarbon titanium ordinarily employed in titanium-treated steels does not serve satisfactorily for such a purpose, under ordinary manufacturing conditions, since the titanium carbides present in the ferroalloy are not readily dissolved in the steel. Even with so-called carbon-free ferrotitanium, favorable conditions were found to be necessary for a reasonably good recovery of the added titanium.

In the five high-speed steels containing titanium which are listed in Table 2, the titanium was added to, and did not replace any portion of, the elements ordinarily present. Three of these steels contained about the customary proportions of carbon, while two others were much higher in carbon content.

With 0.6 to 0.8 per cent carbon and 0.4 per cent or less of titanium the hardness of the steels increased generally with increase in the quenching temperature in much the same manner as corresponding steels without titanium, but the effect of quenching temperature was more marked in the steel containing 0.4 per cent titanium than in that with 0.24 per cent (Fig. 27).

With any one quenching temperature the hardness of the untempered samples decreased as the titanium was increased, and with 1.85 per cent titanium the steel would not harden when quenched from any temperature between 2000 and 2500 deg. fahr.

When the carbon was raised from around 0.7 per cent to 1.2 per cent and the titanium kept at around 1.8 per cent, the steel again hardened upon quenching, the hardness being dependent upon the quenching temperature used. However, with comparable carbon (1.2 per cent) and less titanium (0.29 per cent) the hardness on quenching decreased with increase in the quenching temperature, probably indicating the retention of more austenite. When first quenched from 2000 deg. fahr., samples of this latter steel showed no rehardening on tempering (Fig. 27), as did the samples quenched from 2300 to 2500 deg. fahr.

These results are all shown graphically in Fig. 27 and indicate that the hardness of the quenched steels was not solely a function of the proportion of titanium but depended upon the relative amounts of titanium and carbon present.

The performance of the high-speed-steel tools containing ti-

[3] Would not cut.

tanium and the customary proportions of carbon was disappointing. As shown in Fig. 28, the cutting speeds decreased both with shallow cuts and under heavy duty as the titanium was increased. The steel with about 0.7 per cent carbon and 1.8 per cent titanium which would not harden also failed to cut at the speeds used in the experiments. Tests at lower speeds might

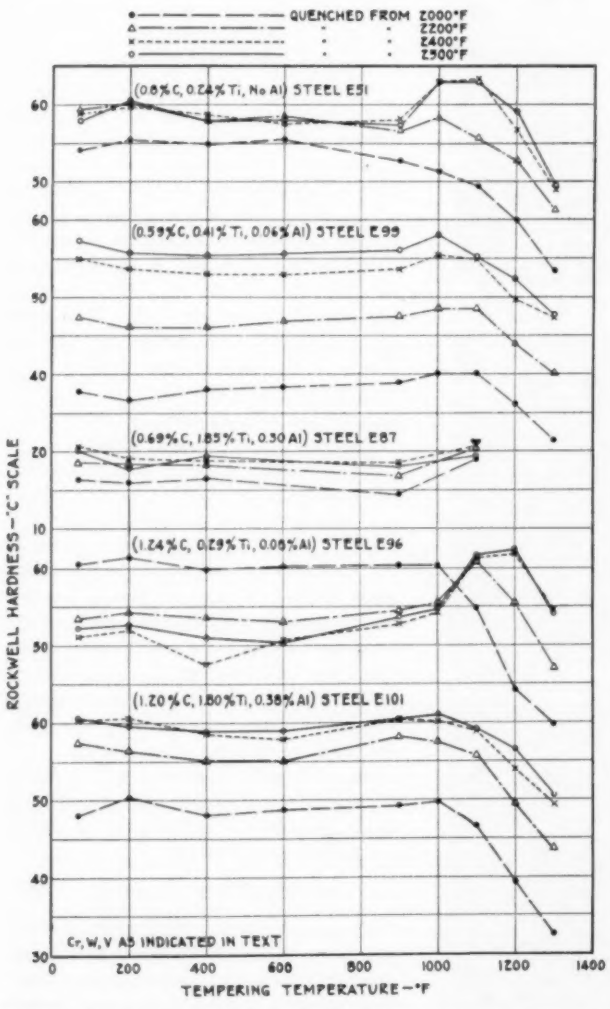

FIG. 27 HARDNESS OF HIGH-SPEED STEELS CONTAINING DIFFERENT PROPORTIONS OF TITANIUM (AND ALUMINUM) WHEN SUBJECTED TO DIFFERENT HEAT TREATMENTS

(Complete chemical compositions are reported in Table 2.)

have resulted in a measurable duration of cut, but for all practical purposes the steel referred to did not have cutting properties comparable to high-speed tool steels.

When the carbon in the steels was raised to 1.2 per cent, increase in titanium from about 0.3 per cent to 1.8 per cent resulted in improved performance both under shallow cuts and under heavy duty. However, the performance of tools of steel E96 may not be characteristic of the reported composition for reasons later explained, but in no case did the steels containing titanium give as good performance as the high-speed steels of customary composition without titanium.

It should be noted that increase in the proportions of titanium resulted in an increase in the proportions of aluminum in the high-speed steels. Aluminum has already been shown to have a highly

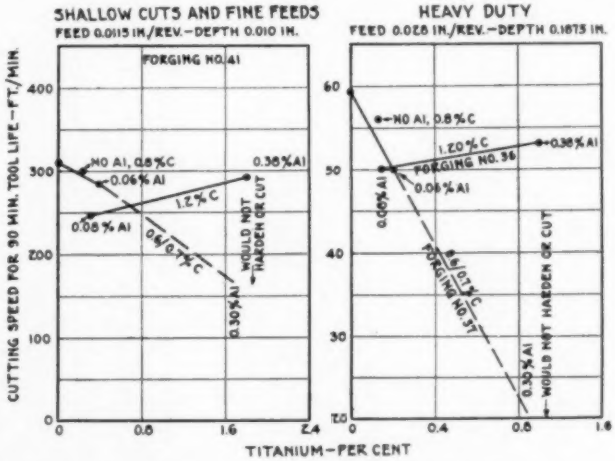

FIG. 28 EFFECT OF TITANIUM (PLUS ALUMINUM) ON THE CUTTING SPEED OF HIGH-SPEED-STEEL TOOLS UNDER SHALLOW CUTS AND UNDER HEAVY DUTY

(Compositions of the tools and their heat treatment are given in Table 2, properties of the forgings are given in Table 3. All tests were made dry.)

deleterious effect upon the performance of high-speed-steel tools, and therefore the changes in the cutting speeds shown in Fig. 28 cannot be ascribed entirely to titanium.

The reductions in the cutting speeds produced by the different proportions of aluminum found in the titanium high-speed steels can be estimated from data given in Fig. 25, and if these reductions in the cutting speed are subtracted from those produced by titanium plus aluminum given in Fig. 28, the effects of titanium alone can be estimated. These calculations are incorporated in Table 15, and show that appreciable proportions of titanium exerted a highly deleterious effect upon the cutting speeds, both with shallow cuts and under heavy duty except in the case of the two high-carbon steels.

While the effects of titanium alone, as given in Table 15, are smaller than those shown in Fig. 28, the estimated corrections for aluminum did not change the general trends shown in Fig. 28.

All of the titanium steels contained characteristic pink or orange-colored titanium inclusions, probably nitrides or cyanonitrides [Figs. 29 (*b*), 29 (*c*), 30 (*b*), 31 (*b*), and 31 (*c*)]. The structure shown in Fig. 30 (*a*) for steel ES7, which could not be hardened appreciably by heat treatment, is probably a solid solution of alpha iron, titanium, and aluminum plus a large number of carbides, tungstides, titanium inclusions, and possibly other undissolved particles.

As the titanium content of the steels was increased, the number of undissolved particles also increased as is shown in Figs. 29(*c*), 29(*f*), and 30(*c*), for the steels containing 0.6 to 0.8 per cent carbon and in Figs. 31(*c*) and 31(*f*) for the steels containing 1.2 per cent carbon. The darkened patches between the grains in the etched sample of steel E101, shown in Fig. 31(*d*), are probably due to the aluminum present and resemble features shown in

Fig. 26 (*c*) for high-speed steel containing about 0.8 per cent aluminum without titanium.

The structures shown in Figs. 29, 30, and 31 indicate that titanium decreases the dissolving capacity of the austenite for the elements which ordinarily are responsible for the characteristic properties of high-speed steels through their solution at high hardening temperatures.

However, titanium is known to form carbides very readily, and in the presence of varying amounts of carbon different effects may be produced. In the presence of high carbon the titanium will probably first form carbides, and any titanium remaining may then go directly into solution in the iron. This of course assumes that there is an excess of titanium available. In the high-speed steel containing 1.2 per cent carbon and 1.8 per cent titanium (E101), the high carbon restored the ability of the steel to harden upon quenching and gave a tool performance nearly equal to that of high-speed steels of customary composition. However, these benefits were probably not derived from any useful alloying effects of titanium but probably were produced by putting the titanium in a less harmful condition (carbides instead of solution in the iron), so that the chromium, tungsten, and vanadium could act in their normal manner.

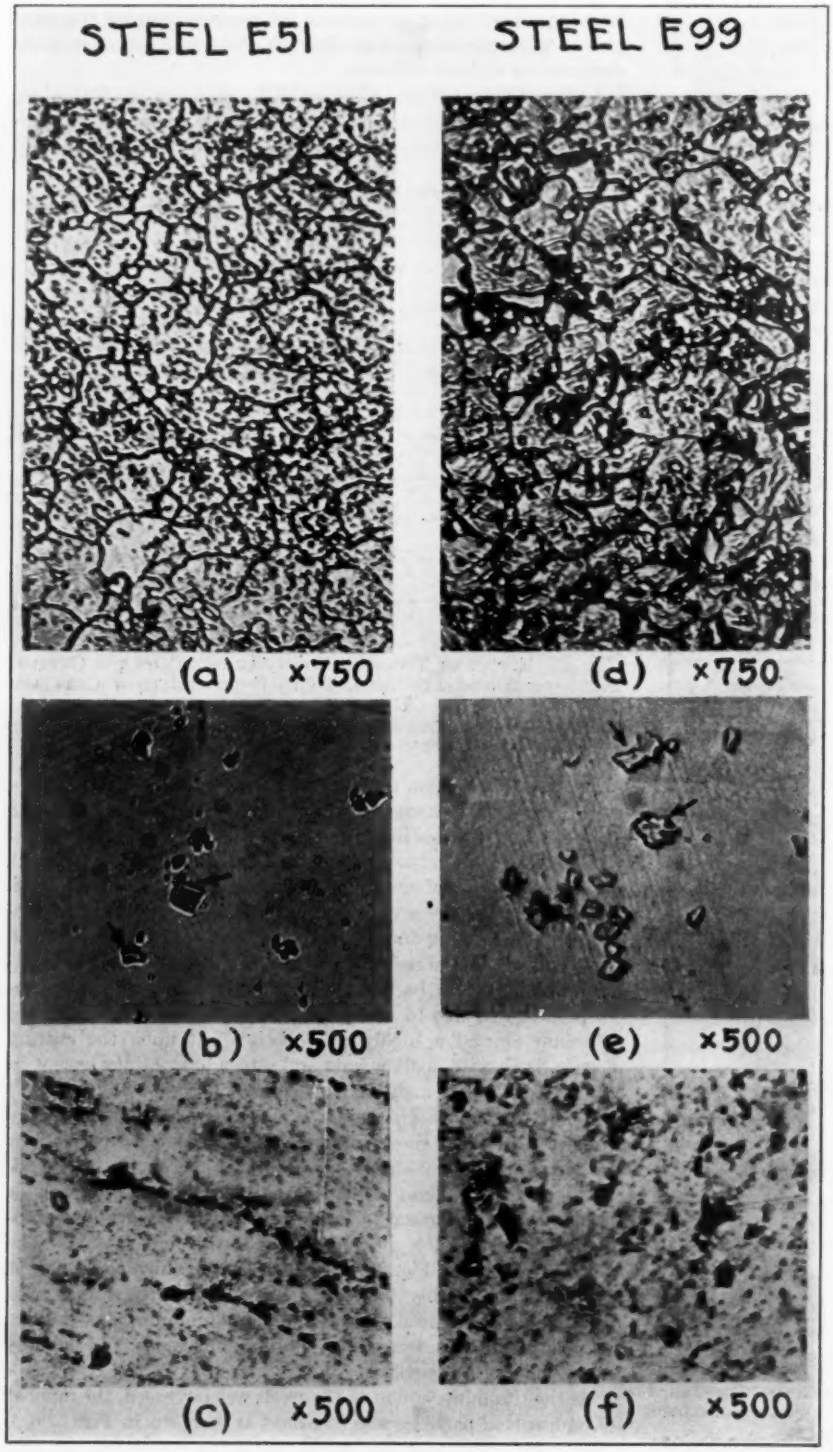

FIG. 29 STRUCTURES OF HARDENED HIGH-SPEED STEELS CONTAINING DIFFERENT PROPORTIONS OF TITANIUM (AND ALUMINUM)

(Compositions of the steels are given in Table 2; *a* and *d* etched with 5 per cent HNO_3 in alcohol; *b* and *e* unetched; *c* and *f* etched in boiling solution of $KMnO_4$ (4 grams), NaOH (4 grams) in 100 cc. H_2O. Samples first oil quenched from 2350 deg. fahr.)

The low cutting speed of the high-carbon, high-speed-steel tools containing only 0.29 per cent titanium cannot be explained at this time, but was probably due either to the high carbon in the absence of appreciable amounts of titanium or to peculiarities of the particular heat from which the tools were prepared. The recovery of titanium in this steel was low, its working properties were poor (Fig. 17), and, as has already been pointed out, it probably had areas of segregation.

Titanium may therefore be considered to be an undesirable addition to the customary high-speed-steel compositions since it probably decreases the dissolving power of the austenite for these compounds which must be brought into solution to produce the properties characteristic of ordinary high-speed steels. Its interference is lessened probably through the formation of less harmful carbides (instead of solution as titanium in the austenite), by increasing the carbon content of the steel. The amount of carbon required will probably vary with the titanium content, and was in the neighborhood of 1.2 per cent carbon for 1.8 per cent titanium.

STEELS WITH TANTALUM

During the year 1924, while a study was being made of the chemical composition of heavy-duty lathe tools, rumors were received that promising results were being obtained in England with high-speed steels containing tantalum. While no details were available, and no performance records could be obtained at that time, a number of experimental steels were made containing different proportions of tantalum and tested in comparison with high-

speed steels of customary composition. The tests were made with deep cuts and coarse feeds, but more recently the same steels were tested under shallow cuts and fine feeds, and a summary of all of the results is now given for the first time.

A report of the preliminary experiments was made in 1925,[52] and discussion of the results brought to light some further information on tantalum in tool steels. One British metallurgist reported[53] that he had made a series of steels presumably with 0.6 per cent carbon, some chromium, and from 1 to 6 per cent tantalum. The steel with 6 per cent tantalum showed properties somewhat similar to the "red hardness" of ordinary high-speed tool steels. In further work, a steel containing about 6 per cent tungsten and 6 per cent tantalum was said to have had about 75 per cent "cutting efficiency" in comparison with the usual tungsten steels.

J. P. Gill[54] reported that during the years 1920–1921, the firm with which he was associated had spent some time in a study of tantalum in high-speed tool steels. He stated that "this company probably made up as many as one hundred different composition high-speed steels containing tantalum, tungsten, chromium, vanadium, and cobalt. Some of the heats made were as large as 7000 lb. Lathe tests were run, many physical tests were made, and it was found that several of the steels compared favorably with some of the regular high-speed steels in commercial use today, but these steels were no better than the same steels without tantalum. We did not find any steels that were better than the regular high-speed steels. Many things were learned in regard to the use of tantalum. The manner of introducing the tantalum into the steel and the form of the tantalum in the alloy apparently affected the results. The tantalum steels were found to be very dirty and full of oxides even when melted under the best of conditions. Even in view of this fact, however, the tantalum steels seemed to be tougher than the standard types of high-speed steel."

Studies of tantalum in carbon steels have been reported by Guillet,[55] Portevin,[56] and others[57] but these investigations do not throw much light upon the subject under discussion. Apparently tantalum up to at least 8 per cent in iron-carbon alloys is in solution in the ferrite, and with carbon up to 0.6 per cent the steels are pearlitic on normal slow cooling and martensitic after quenching. The effects of tantalum on steels which are suitable for cutting tools are not generally known, although a few patents, typified by that granted to F. T. McCurdy,[58] indicate that tantalum may be useful in this field.

The seven steels containing tantalum that were tested fall into three classes. Steel E23, Table 2, is a chromium-tantalum steel similar to one previously mentioned as having been made experimentally in England. Steel E42 is a chromium-tungsten-vanadium steel in which about 6 per cent of tungsten was replaced by 6 per cent of tantalum. The steels E43, E44, and E16 contained the usual proportions of special elements, except that the vanadium was replaced by different proportions of tantalum. The results obtained with these three steels suggested that increased carbon might improve the properties, and accordingly two similar steels were made, E45 and E100, Table 2, with 0.9 and 1.4 per cent carbon, respectively.

A study was first made of the hardness of the different steels after different heat treatments and developed some interesting characteristics. There was no evidence of rehardening on tempering of the chromium-tantalum steel, E23, as is shown in Fig. 32.

The hardened samples appeared to be predominately martensitic with some undissolved particles, probably chromium carbides, as is shown in Figs. 33 (*a*), (*b*), and (*c*). Steel E42 would not harden appreciably under any of the heat treatments em-

ployed. These included oil and water quenching from temperatures varying from 1500 to 2500 deg. fahr., followed by tempering at different temperatures up to 1400 deg. fahr. for periods up to 195 hours. The long-time tempering was carried out to ascertain whether any precipitation hardening would occur. The structure of this steel when quenched from 2350 deg. fahr. into oil is shown in Figs. 33 (*d*), (*e*), and (*f*), and comprised a large number of undissolved particles, probably carbides and tungstides in a matrix of alpha iron (Rockwell C hardness about 27) presumably containing tantalum in solid solution.

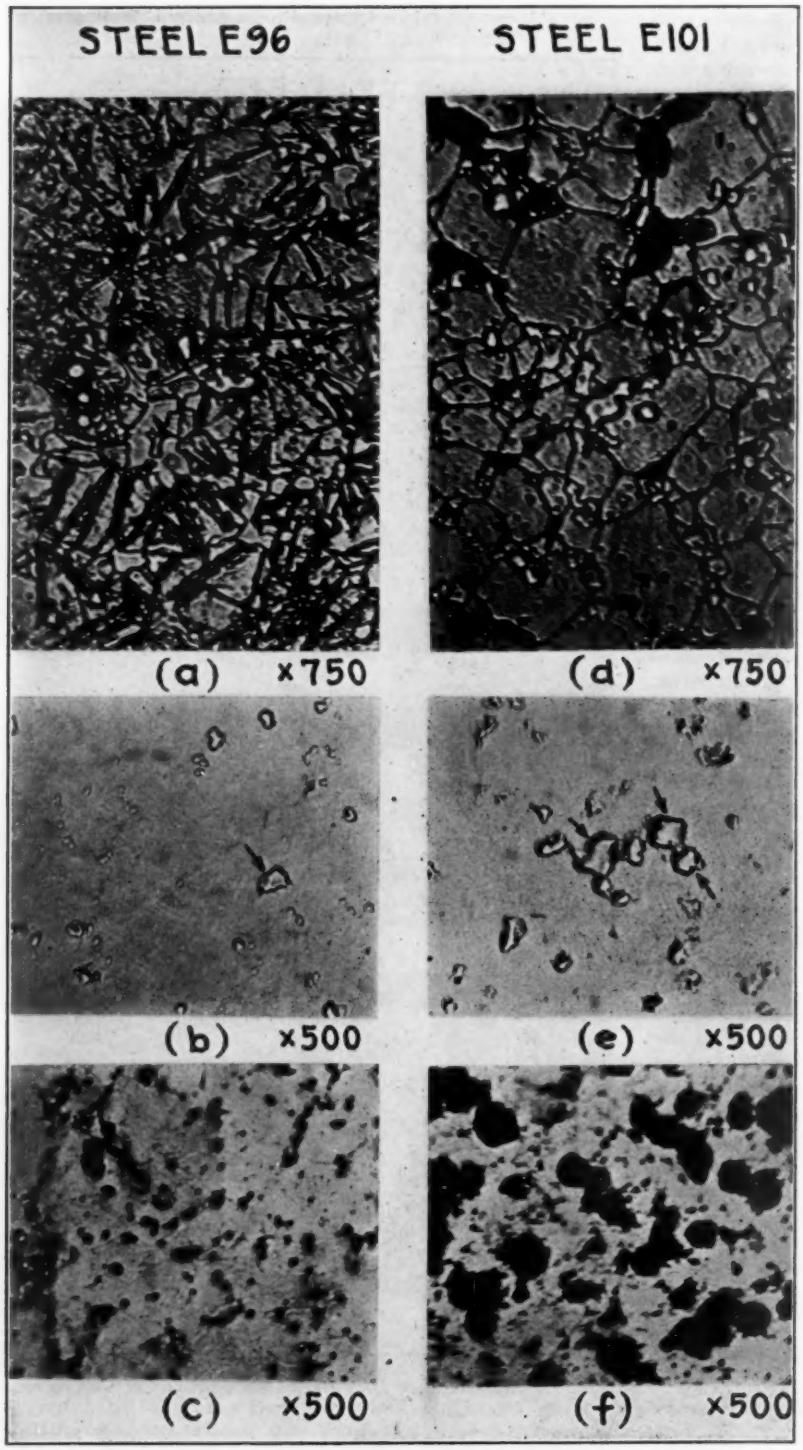

FIG. 31 STRUCTURES OF HARDENED HIGH-SPEED STEELS CONTAINING ABOUT 1.2 PER CENT C AND DIFFERENT PROPORTIONS OF TITANIUM (AND ALUMINUM)

(Compositions of the steels are given in Table 2; *a* and *d* etched with 5 per cent HNO_3 in alcohol; *b* and *e* unetched; *c* and *f* etched in boiling solution of $KMnO_4$ (4 grams), NaOH (4 grams) in 100 cc. H_2O: Samples first oil quenched from 2350 deg. fahr.)

The hardness of the steels containing the usual proportions of carbon, chromium, and tungsten (low-tungsten–high-vanadium steels) was not greatly affected under different heat treatments by 0.75 per cent or less of tantalum, except that the maximum rehardening on tempering occurred at about 1000 to 1050 deg. fahr. instead of at 1100 deg. and that the hardness of the tempered samples did not quite equal the highest hardness produced in the untempered samples. Also in the untempered samples the hardness tended to decrease with increase in quenching temperature. (Fig. 34.) With 5 per cent tantalum the hardness was less than that of the high-speed steels of customary composition when subjected to comparable heat treatments, and the hardness was more largely dependent upon the quenching temperature.

As shown in Fig. 35, the number of undissolved particles increased with increase in the tantalum. This was probably not due to any combination of tantalum and carbon, but to a decrease in the dissolving power of the austenite for the chromium and tungsten carbides, or tungstides, produced by the tantalum in solution in the iron.

The hardness and the structures (Figs. 32 and 36) of the chromium-tungsten-tantalum steel E45, containing 0.9 per cent carbon, were approximately the same as those of the chromium-tungsten-tantalum steels with 0.6 to 0.7 per cent carbon.

Perhaps the most interesting of the steels containing tantalum in addition to the customary amounts of chromium and tungsten was the one containing 1.4 per cent carbon (E100, Table 2). As shown in Fig. 32, this steel had a Rockwell C scale hardness of only about 36 when oil quenched from temperatures between 2200 and 2500 deg. fahr. When hardened from a lower temperature, 2000 deg. fahr., its hardness was about 56 and was not appreciably changed upon subsequent tempering at temperatures up to 1100 deg. fahr.

The samples which did not harden when oil quenched from 2200 to 2500 deg. fahr. did not harden appreciably when subsequently tempered at temperatures up to 1000 deg. fahr., but with increase in tempering temperature to 1100 deg. fahr. showed a surprisingly large increase in the hardness. This increase on the Rockwell C scale was from about 40 to 62, a difference of 22 points. The untempered samples showed an austenitic matrix with numerous undissolved particles at the austenite grain boundaries as is shown in Figs. 36(*d*), (*e*), and (*f*).

None of the steels containing tantalum showed as good performance as the high-speed steels of customary compositions, either with shallow cuts and fine feeds or under heavy duty. Steel E42, which would not harden, also failed to cut. Likewise the chromium-tantalum steel E23 did not show cutting properties comparable to those of the ordinary high-speed steels. The results of the lathe tests with these steels are summarized in Table 16.

The high-carbon, chromium-tungsten-tantalum steel, E100 (Table 2), which showed the very large increase in hardness when tempered at 1100 deg. fahr. after quenching from high temperatures failed to show any promise for lathe tools for either shallow cuts or heavy duty. As shown in Table 16, the tools failed in less than one minute, whereas the high-speed steels of customary composition cut for periods of 10 to 22 min. under comparable conditions. The best tool life (3.6 min.) in rough turning was obtained when steel E100 was oil quenched from 2400 deg. fahr. and subsequently tempered at 1100 deg. fahr.

The four high-speed steels containing 0.6 to 0.9 per cent carbon, in which the 2 per cent of vanadium was replaced by different proportions of tantalum, gave the best tool performance of any of the steels containing tantalum, but in no case was this as good as the performance of the customary chromium-tungsten-vanadium steel. As shown in Fig. 37, the cutting speeds of the chromium-tungsten-tantalum steels decreased with increase in the proportion of tantalum.

Tantalum does not appear to be promising as a substitute for vanadium or as an alloying element in the customary chromium-tungsten high-speed steels for lathe tools. It acted in a manner similar to aluminum and titanium in that it appeared to decrease the dissolving power of the austenite for the chromium and tungsten compounds, and so decreased the hardness and cutting speeds of the quenched lathe tools.

Steels With High Phosphorus or Sulphur

Phosphorus and sulphur are present in varying proportions in all commercial steels, and therefore it seemed desirable to determine their effects upon lathe-tool performance in connection with the study of impurities in high-speed steels for shallow cuts, already described. Furthermore, relatively large proportions of phosphorus or sulphur were inadvertently introduced, through one of the lots of ferrovanadium into some of the high-speed steels containing nickel or cobalt, and it became impracticable to interpret the results of the lathe tests with these steels without information on the effects of the phosphorus and sulphur present.

As a result of their extended experiments with roughing tools, Taylor and co-workers[59] came to the conclusion "that high phosphorus and sulphur are much less injurious to high-speed tools than they are to the carbon tools. However, these elements still exert a somewhat injurious influence upon the steel, and we therefore recommend, inasmuch as the presence of chromium and tungsten in large quantities necessarily renders high-speed tools very expensive, that the best qualities of low-phosphorus and low-sulphur iron should be used in their manufacture."

These views have received the support of a majority of the American manufacturers of high-speed tool steels, as is shown by the results of a survey made during 1922[60] of 66 lots representing

[1] Computed from average tool life by means of Equation [1] of the text with $n = 1/10$ for shallow cuts and $n = 1/7$ for deep cuts.
[2] Tests made at 75 ft. per min.

39 commercial brands on the American market. The average proportions of phosphorus and sulphur were 0.023 per cent and 0.027 per cent, respectively, while the ranges were 0.004 to 0.051 per cent phosphorus and 0.009 to 0.061 per cent sulphur.

Comparison of the results in Fig. 38 with those for steel E97 in Fig. 23, shows that the Rockwell hardness of the high-speed steels was not appreciably affected by 0.058 per cent added phosphorus or 0.215 per cent added sulphur. However, the high-sulphur steels showed a large number of sulphide inclusions, Figs. 42(*a*) and (*b*), and 40, and there was evidence of phosphide-rich areas in the steel with 0.058 per cent phosphorus, Fig. 42(*c*).

The sulphide inclusions in the chromium-tungsten-vanadium steels were probably sulphides of both manganese and iron, since the 0.39 per cent manganese in steel E133 is not sufficient to take care of all of the 0.215 per cent sulphur. Similar sulphide inclusions were found in the high-sulphur high-speed steels containing nickel, although they did not have as smooth boundaries as in the steels without nickel and were interspersed with, or broken up by, white constituents, presumably the carbides and tungstides. It is possible that some of the sulphur has combined with the nickel in the high-speed steels containing this latter element, but definite evidence is lacking that this is so, and the significance, if any, of these differences in structural characteristics is not now apparent. The feature of principal interest is that evidence was obtained in the lathe tests that high sulphur was somewhat more detrimental in the high-speed steels with nickel than in those without.

In the lathe tests under heavy duty and also those under shallow cuts, summarized in Fig. 39, the steel with 0.058 per cent phosphorus (E131, Table 2) and the steels with 0.135 and 0.215 per cent sulphur showed comparable performance to the steels with much lower proportions of these elements (E129 and E97). Similarly a cobalt high-speed steel with both high phosphorus and high sulphur (E15) had a cutting speed equal to that of a similar steel with low phosphorus and sulphur (Steel A, Table 2). On the other hand, the nickel-bearing high-speed steel with 0.057 per cent phosphorus and 0.125 per cent sulphur had a lower cutting speed than similar steel with about 0.02 per cent of each of these elements.

It may therefore be said that phosphorus up to about 0.06 per cent and sulphur up to 0.215 per cent do not appear to be injurious, from the viewpoint of lathe-tool performance, when present individually or together, in the customary chromium-tungsten-vanadium steels, with or without cobalt. However, high sulphur tended to lower the cutting speeds in the presence of nickel.

Because of the possibility of segregation of the phosphorus and the introduction of numerous sulphide inclusions in high-sulphur steels, these two elements may react disadvantageously by promoting lack of uniformity and localized weaknesses. Therefore they can advisably be kept within low limits for all high-speed-steel lathe tools.

(Compositions of the steels are given in Table 2; *a* and *d* etched with 5 per cent HNO_3 in alcohol; *b* and *e* unetched; *c* and *f* etched in boiling solution of $KMnO_4$ (4 grams), NaOH (4 grams) in 100 cc. H_2O.)

Steels With Nickel

The close proximity of nickel and cobalt in the periodic system of the elements and recognition of the benefits derived from cobalt has frequently raised the question of substituting nickel for cobalt in high-speed tool steels.

Previously reported tests with roughing tools[61] showed that the addition of about 3¾ per cent of nickel to the customary chromium-tungsten-vanadium steels produced effects similar to those from like amounts of cobalt. However, in hardening somewhat higher temperatures had to be used for the nickel steels than for the steels without nickel to produce the best tool performance, and in this respect nickel and cobalt acted similarly. On the other hand, it was more difficult to put the high-speed steels with nickel into a machinable condition than it was with steels containing cobalt or steels without nickel or cobalt, unless an adjustment was made in the carbon content. With decrease in carbon from 0.6 or 0.7 per cent to 0.5 per cent the steels with nickel could themselves be readily machined, while the tool performance under heavy duty remained substantially the same.

These tests were all made under heavy duty and two of the nickel steels contained high phosphorus or sulphur, or both. For this reason the rough-turning tests were repeated on steels containing low proportions of phosphorus and sulphur and the results are included in Table 17 with those obtained under shallow cuts and fine feeds.

The results in Table 17 shows that the addition of 3¾ per cent of nickel to the customary chromium-tungsten-vanadium steels was beneficial for the rough-turning tools but detrimental to the tools under shallow cuts and fine feeds.

In the rough-turning tools the addition of nickel together with a 50 deg. fahr. increase in the quenching temperature produced an appreciable improvement in the performance of the high-speed steels, but the same tools were not as good under shallow cuts as the tools free from nickel which were hardened at lower temperatures.

The fact already mentioned that the high-speed steels with nickel could not themselves be readily machined, even after prolonged annealing, suggested lowering the carbon content from around 0.6 or 0.7 per cent to 0.5 per cent.

This did not affect the performance of the roughing tools appreciably, as is shown in Table 17, but was detrimental in the tools used under shallow cuts.

[61] See footnote 27.

XII—SUMMARY AND CONCLUSIONS

1 A method is described for testing lathe tools under shallow cuts and fine feeds. It is based upon the fact that when two tools are set at equal depths in one tool holder the second or "trailing" tool will not cut so long as the "leader" or cutting tool shows no wear. With the carbon- and high-speed-steel tools used, the second tool began to cut when the leader had worn 0.001

[1] All tools annealed at 1600 to 1650 deg. fahr.; tempered 30 to 45 min. at 1100 deg. fahr. after hardening.

[2] Computed from Equation [1] of the text with $n = 1/7$ for deep cuts and $n = 1/10$ for shallow cuts.

All tests made dry with tools of the form shown in Fig. 5. The tests in each block constitute a complete run at one time in sequence at different diameters of the test forgings.

to 0.002 in., and at this point the leader or test tool was considered to have failed. All subsequent comments on turning with shallow cuts and fine feeds are based on this end point, but greater wear can be made to represent tool failure by using a shallower setting for the second tool than is used for the cutting tool.

2 Tests were made dry at different cutting speeds, feeds, and depths of cut on nickel-steel forgings with tensile strengths of 80,000 to 100,000 lb. per sq. in. to give a broad background for the interpretation of the results of tests of different tool steels, first heat treated in various ways. The results could be represented approximately by the following equations in which V is the cutting speed, T the tool life, F the feed, D the depth of cut, A the area of cut ($=DF$), and c, K, K_1, K_2, and n are constants.

For high-speed-steel tools,

$$VT^{1/10} = c \quad [1]$$

$$V = K_1 - K_2(DF) = K_1 - K_2A \quad [2]$$

For carbon-steel tools,

$$V = \frac{K}{DF} = \frac{K}{A} \quad [3]$$

These equations are not to be construed to represent the true laws of cutting since the cutting speed is probably not affected equally by variations in the feed and the depth of cut. However, they represent approximately the results of the experiments made with depths of cut of 0.005 to 0.020 in. and feeds of 0.0115 to 0.0204 in. per rev.

3 In tests of short duration, where tool failure occurred in about 2 to 10 min. the tool life was increased somewhat more by the use of water than by lard oil, but in tests of about 50 min. duration, under the same feed and depth of cut but lower cutting speeds, these two liquids produced effects of the same magnitude. The increases in tool life from the use of these liquids were not large in any case, but the finish on the work piece at the end of the cut was better with the liquids than without.

4 Tests with tools of different forms and angles showed that the successful application of the described method of test was not dependent upon having the broad-nose tool used in a majority of the experiments. Tools with a plan angle of 65 deg. had a longer life than the broad-nose tools, but the finish produced on the nickel steels in dry turning did not appear to be as good. The best tool life in the broad-nose tools was obtained with a back slope of 30 deg.; a side slope of 0 deg. was better than one of 8 deg.

5 The cutting speed of quenched carbon-steel tools was not affected appreciably by variations in carbon content from 0.75 per cent to 1.3 per cent nor by subsequent tempering at temperatures up to 375 deg. fahr., which did not lower the hardness; the cutting speed of the carbon-steel tools was equal approximately to that of a quenched "oil-hardening" tool steel, and only slightly lower than the cutting speed of a steel containing 1.3 per cent carbon and $2^3/_4$ per cent tungsten.

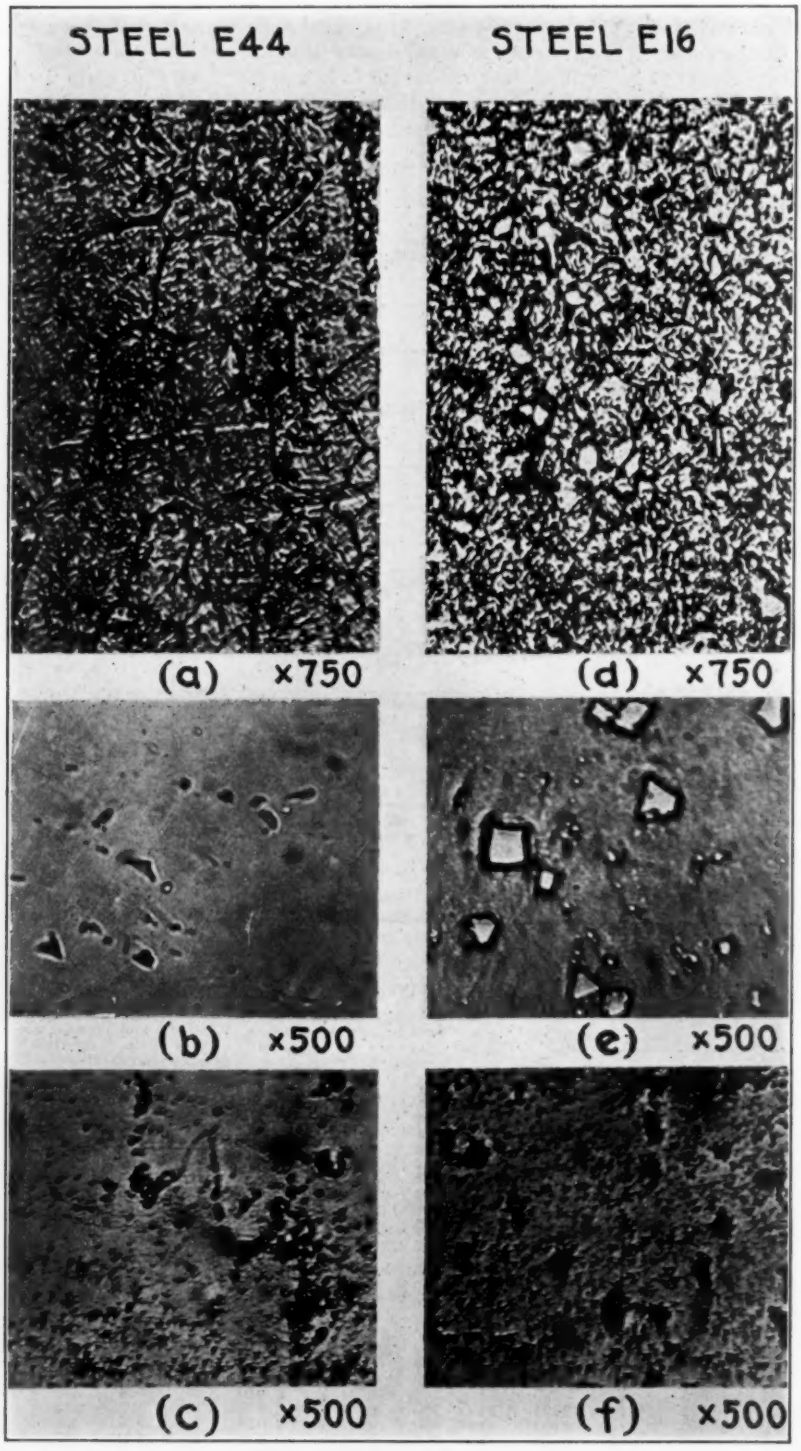

FIG. 35 STRUCTURES OF TWO OF THE CHROMIUM-TUNGSTEN-TANTALUM STEELS AS OIL QUENCHED FROM 2350 DEG. FAHR.

(Compositions of the steels are given in Table 2; *a* and *d* etched with 5 per cent HNO_3 in alcohol; *b* and *e* unetched; *c* and *f* etched in boiling solution of $KMnO_4$ (4 grams), NaOH (4 grams) in 100 cc. H_2O.)

6 The cutting speed of carbon-steel tools was lower in all cases than that of high-speed-steel tools, but the differences between the two decreased with decrease in the areas of cut in dry turning.

7 The heat treatments which resulted in the best roughing-tool performance for high-speed steels of customary compositions also resulted in superior performance under shallow cuts and fine feeds. These treatments comprised oil quenching from the highest practical temperatures, followed by tempering to convert the larger part of the retained austenite to martensite.

8 Of twelve elements added in different proportions to chromium-tungsten or chromium-tungsten-vanadium high-speed steels only one, cobalt, produced decidedly beneficial results. Molybdenum and nickel offered promise under certain conditions, while the remainder either had a negligible effect or were definitely deleterious from one viewpoint or another.

9 Cobalt improved the performance of the high-speed-steel tools both under shallow cuts and under heavy duty, but the maximum benefits were obtained only with high hardening temperatures. The percentage gain from the addition of cobalt was somewhat greater in rough turning than with shallow cuts and fine feeds, but increase in cobalt above about 5 per cent did not produce improvements commensurate with those resulting from 3.5 to 5 per cent and high hardening temperatures.

10 Replacement of part or all of the tungsten in high-speed steels by molybdenum, in the ratio of 1 part molybdenum to $2^1/_2$ parts of tungsten, produced steels having performance comparable to that of the tungsten steels. Such substitution should be useful in case of a depleted tungsten supply, but is not advocated at the present time since there was some evidence of irregular performance in the high-molybdenum steels and their hot-working properties did not seem to be as good as those of the tungsten steels. However, a steel with 7 per cent molybdenum and no tungsten had one advantage over the tungsten steels for roughing tools in that its hardness and performance were not so largely affected by variations in the hardening temperatures.

11 The addition of $3^1/_4$ per cent of nickel to the customary chromium-tungsten-vanadium steels was beneficial for the rough-turning tools, particularly when combined with a 50 deg. fahr. increase in the hardening temperatures, but was detrimental to the tools used under shallow cuts and fine feeds and adversely affected the machining properties of the high-speed steel itself. Lowering the carbon from 0.6 or 0.7 per cent to 0.5 per cent improved the machining properties without affecting the performance of the roughing tools, but was detrimental to the tools used under shallow cuts.

12 Each of the four elements, arsenic, antimony, copper, and tin, adversely affected the tool performance of high-speed steels under shallow cuts, and the magnitude of the decrease became greater as the proportions of these elements increased. Copper

(Compositions of the tools and their heat treatments are given in Table 2; properties of the forgings are given in Table 3. All tests were made dry.)

was the least harmful; next in order came tin, while arsenic and antimony were the most objectionable.

13 The effects of these four elements upon the performance of roughing tools did not necessarily correspond to those observed with shallow cuts. The 0.8 per cent arsenic additions lowered the cutting speed, but the addition of 0.4 per cent antimony or 0.5 per cent or less of tin had no measurable effect. Higher proportions of tin lowered the cutting speeds. The high-speed steels containing 0.36 to 1.77 per cent copper showed slightly better performance than the corresponding steels without copper.

14 The steels containing 0.4 per cent antimony, 0.8 per cent or more of copper, or 0.8 per cent arsenic did not have good hot-working properties, illustrated by numerous corner cracks on the bars, while those containing 1.7 per cent antimony or 1.8 per cent tin showed a high degree of hot shortness and could not be forged or rolled. Also the steel with 1.77 per cent copper could itself be machined only with difficulty in the annealed condition.

15 Phosphorus up to about 0.06 per cent and sulphur up to 0.215 per cent did not appear to be injurious, from the viewpoint of lathe-tool performance of the customary chromium-tungsten-vanadium steels, with or without cobalt. However, high sulphur tended to lower the cutting speeds in the presence of 3¾ per cent nickel. Because of the possibility of segregation of the phosphorus and the introduction of numerous sulphide inclusions in high sulphur steels, these two elements can advisedly be kept within low limits for all high-speed-steel lathe tools.

16 Aluminum adversely affected the performance of the high-speed-steel tools both with shallow cuts and under heavy duty. It was one of the few metals considered which, in proportions around 0.3 per cent produced a measurable decrease in the cutting speeds in rough turning. This decrease became greater as the proportion of the aluminum was increased, and with 0.8 per cent the drop in cutting speed was greater than that produced by equal proportions of any of the other elements considered. These changes were accompanied by decrease in the hardness of the quenched steels, probably through decrease in the dissolving capacity of the aluminum-iron solid solution for carbon, chromium, tungsten, and vanadium. With 0.8 per cent aluminum there was also evidence of a low-melting eutectic in samples quenched from 2350 deg. fahr.

17 Titanium was another of the elements which appeared to lower the dissolving capacity of the austenite, and as a result the hardness and the cutting speeds of the high-speed-steel tools decreased with increase in the titanium. Its interference was lessened, probably through the formation of less harmful carbides, instead of solution as titanium in the austenite, by increasing the carbon content of the steel.

18 Tantalum did not appear to be promising as a substitute for vanadium or as an alloying element in the customary chromium-tungsten high-speed steels for lathe tools. It acted in a manner similar to aluminum and titanium in that it appeared to decrease the dissolving power of the austenite for the chromium and tungsten compounds and so decreased the hardness and cutting speeds of the quenched lathe tools.

XIII—ACKNOWLEDGMENTS

Acknowledgments are due to a number of the authors' associates as follows: to C. F. Raab, machinist, whose care in grinding all of the tools and help in carrying out many of the lathe tests contributed appreciably to the consistent results obtained; to W. V. Magruder, laboratory aid, for carrying out many of the heat treatments, as well as hardness and lathe tool tests; to H. K. Herschman, associate metallurgist, and S. J. Rosenberg, assistant metallurgist, for the preparation of the micrographs; and to H. Bright, associate chemist, for the chemical analysis of the tools that were necessary for the work of carrying on the various operations.

Discussion

ORLAN W. BOSTON.[62] Unquestionably the paper furnishes information on the subject of turning with shallow cuts at high speeds which has long been needed. It seems rather unusual that the results of the dynamometer tests to show a relation between vertical or horizontal forces on the tool and the tool life

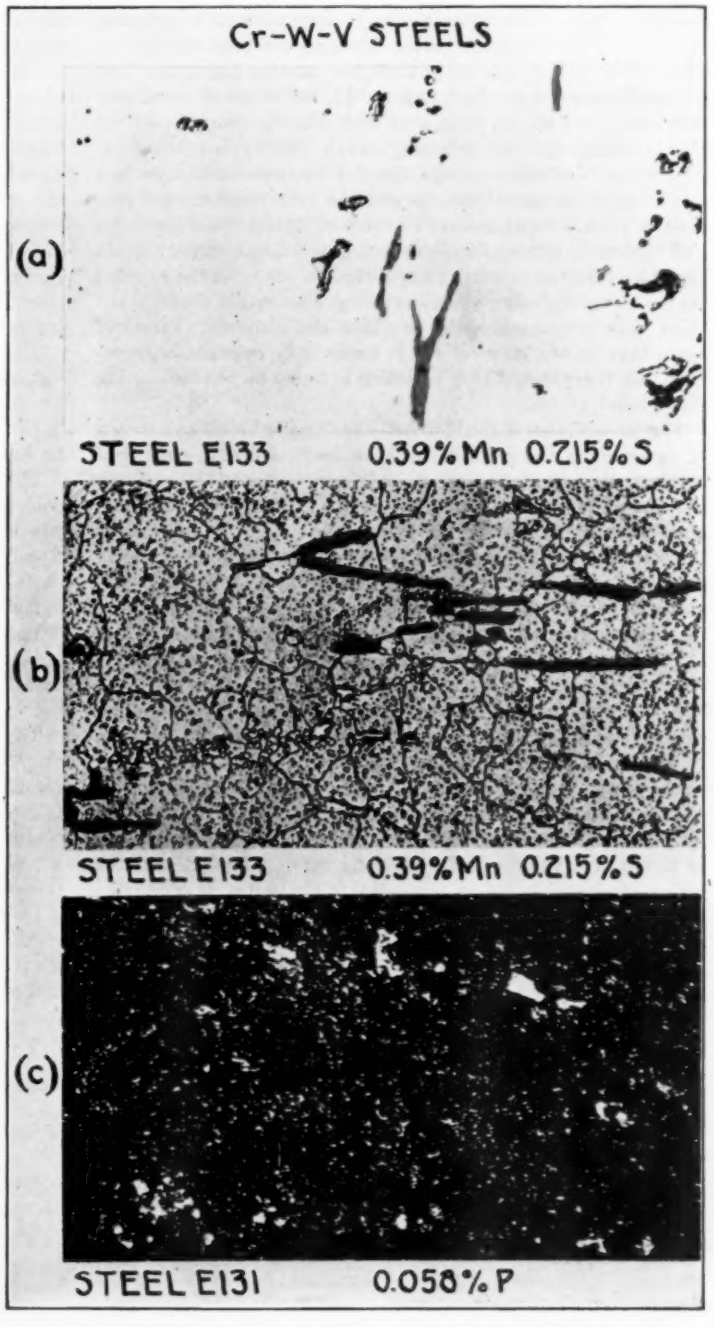

FIG. 42 STRUCTURES OF HARDENED HIGH-SPEED STEELS CONTAINING HIGH PHOSPHORUS OR HIGH SULPHUR ×500

[62] Professor of Shop Practice, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

were not more decisive. Obviously, during the wear of the tool the shape of the tool is altered. Where a ductile material is cut the tool failure is usually a result of a cupping action which wears gradually toward the cutting edge until the cutting edge is insufficiently supported. During this cupping action the rake, back of the cutting edge, is very materially increased up to the point of failure or the breaking down of the cutting edge. The writer has no information on this point, but has observed many times in turning with rather small cuts, say 0.100 in. by 0.0125 in. feed, that with a newly ground tool the chip is stringy and not definitely coiled. This chip is also blue. As the tool face begins to cup, the chip becomes broken up into small helical or spiral sections and the blue color merges into a straw color. Further wear of the tool causes the chips to be well broken up into small spirals and practically colorless. This condition maintains during most of the tool life. As the cupping nears the cutting edge and the cutting edge spalls slightly, the chips again become irregular in shape and somewhat torn and again take on the blue color. It seems only reasonable, therefore, that there should be a variation in forces on the tool during this whole process.

The introduction of the "leader" and "trailer" tools as a means of determining the point of tool failure in finishing cuts is of considerable importance, as no satisfactory way of determining the time of failure has previously been reported. The question may be asked as to why the broad-nosed tool was selected as the form for the best tool. This form does not seem to be of general use commercially. The results, however, would apparently not be altered by the use of this shape, as the other tool shapes give similar but slightly different values.

The results showing the effect of cutting speed on tool life show some variation in the exponent of the equation $VT_n = c$. The writer wonders if this variation is not due to the actual cutting condition rather than to experimental error; that is, is there not a gradual merging of the value of the exponent from $^1/_7$ for roughing cuts to $^1/_{12}$ for finishing cuts, and if so, what is the nature of this merging curve, and how is it influenced by depth and feed? There still appears to be some question as to the final value of n for finishing cuts. The fact that the carbon-steel tool failed in less than five minutes or continued to cut for 90 or more minutes without sign of failure is again a matter which should be explained further.

It is perhaps unfortunate that the authors did not carry out their experiments a little further with a view to establishing the laws of cutting with particular reference to the influence of the depth and feed which make up the cross-sectional area of the chip. Apparently not much greater experimental work would have been needed. This question is continually raised. Taylor's work, in spite of its age, is still one of the leading forces tending to show the influence of each of the variables rather than their product. This point has been discussed very competently by George Kiebel, M.E., of the Eastern Chinese Railway,at Harbin, in a paper, "Diagrams for Metal Turning Lathes," giving a precise method of the most advantageous utilization of tool and lathe as reported to a technical meeting of the Engineers Locomotive Society of the Chinese Eastern Railway on January 5, 1929. In this paper Mr. Kiebel lays great emphasis on the independent use of the depth and feed, rather than the area of cut. It is known that thick chips are removed more efficiently considering power than thin ones, and yet it is also known, as pointed out under the conclusions of Ripper and Burley, on the seventh page, that if the area of cut is kept constant, a higher associated cutting speed is obtainable when the cut is deep and the feed fine.

The authors' conclusions as to the effect of feed, depth of cut, and area of cut on the cutting speed for a 90-minute tool life for carbon-steel tools are extremely interesting. The relation of these curves to those for high-speed steel tools should be continued for smaller cuts.

The authors' conclusions as to the influence on tool life of back and side slope are also interesting. It is not clear, however, whether it is meant that the tool having the greatest speed for 90-minute tool life is one having 0-deg. side slope and 30-deg. back slope or whether these optimum angles were determined independently. If they were determined independently, might it not be possible that their combination might not yield the optimum results? The power would be lowered still further with an increase in the true rake, so it must be concluded that the "power" and "tool-life" factors of a tool are not in agreement.

The investigation on the influence of a coolant, representing each of the three general classes, corresponds in general with the results previously reported by the authors for rough cutting. It is unfortunate that further work was not done to determine positively the influence of the coolants on the cutting speed for a tool life greater than 50 minutes. This undoubtedly will be the subject of further investigation.

In general, the writer feels that the authors are to be commended on the thoroughness of their investigation and the clear manner in which their results are presented. Certainly, many of the points about metal cutting under the conditions of fine cuts have been cleared up and a great deal of definite information has been added to the long story of metal cutting.

MSP-52-7

A Study of Tin-Base Bearing Metals—II

By G. B. KARELITZ,[1] EAST PITTSBURGH, PA., and O. W. ELLIS,[2] TORONTO, ONT.

This paper is a continuation of one presented by the authors at the Pittsburgh Meeting of the A.S.M.E. in 1928, and deals with the mechanism of wiping of babbitt linings, with certain phenomena observed during the casting of tin-base alloys, and with the effects of cold work on them. It is shown that wiping of babbitts is a result of the upper layer of the lining's reaching the solidus temperature, when the constituent with the lowest melting temperature liquefies, the babbitt becomes "mushy," and is therefore wiped by the journal. The appearance of the castings of various chemical composition is discussed, and the variation in hardness and microstructure due to cold work is given.

THE authors' paper on the properties of tin-base bearing metals presented before the Society in 1928[3] dealt with the metallurgical investigation of a series of alloys of tin, antimony, and copper, and with the strength of these alloys at low and elevated temperatures. This second part of the study concerns itself with the nature of babbitt failure in bearings, which generally takes the form of "wiping." It can be observed in bearings, during the early stages of failure, that metal is dragged along by the journal. Frequently beads of metal are present, which, it appears, would indicate that melting has taken place. However, it has not hitherto been proved whether melting is the cause of wiping or is a result of a temperature rise following the destruction of the bearing surface and a consequent increase of friction. The latter is considered to be feasible, since it has been shown that babbitts lose their strength to a marked degree at temperatures above, say, 100 deg. cent. It seemed probable that should an occasional disturbance in lubrication take place and high local friction occur in a spot of metal-to-metal contact, the babbitt might be heated and, getting weak, be "cold worked" by the journal.

Apparatus Used for Experiments

The testing machine shown in Figs. 1 and 2 was designed with a view to approximate as closely as practicable the conditions of wiping in actual bearings. The test journal had an interchangeable outer sleeve in order to allow various shaft materials to be employed. In the tests described below a standard shaft material was used, having a composition: C, 0.3 to 0.4 per cent; Ni, 1.0 to 1.5 per cent; Cr, 0.45 to 0.75 per cent; Mn, 0.5 to 0.8 per cent; P, 0.04 per cent maximum; S, 0.045 per cent maximum. The journal was ground true to 0.0002 in. It was mounted on roller bearings and was connected by a flexible coupling to a variable-speed motor. A wide range of speeds was attained by the use of Ward Leonard control. A recording torsiometer was provided which could be mounted in place of the coupling; however, it was found that for the work at hand sufficient accuracy could be obtained by recording the field and armature currents in the motor, which was carefully calibrated for torque.

The test bearings were mounted in a very rigid frame made in two halves bolted together. The load was applied through a spring dynamometer, the maximum load being 5000 lb. A flexible arrangement of the loading gear excluded eccentricity of load application, while transverse stops on the frame prevented vibration in the event of resonant condition occurring.

The test bearings (Fig. 3) were made of bronze lined with the materials under test. The diameter of the journal was 5.000 in. The length of the bearings was 2 in., the bearing being in fact a rather narrow ring split in two on its diameter. This shape was chosen to insure the absence of an efficient load-carrying oil film and the prevalence of boundary lubrication, these test conditions being of most interest to the authors. As seen in Fig. 4, the bearings were placed in the frame with the split at an angle of 30 deg. to the frame joint. Lubrication was supplied through a hole registering with a duct in the frame by an oil cup through a needle valve. The oil cup was calibrated and the oil feed could therefore be conveniently regulated.

The bearings were machined to a clearance of 0.011 in. within an accuracy of ±0.003 in. The influence of temperature on the clearance was checked by consecutive heating and cooling of the bearing frame with an unbabbitted ring assembled in it, a glycerine bath being used for heating; the inner diameter of the bearing was measured in hot and cold condition. Table 1 gives these measurements.

TABLE 1 INFLUENCE OF TEMPERATURE ON BEARING CLEARANCE

Condition of frame	Diameter normal to ring split, in.	Diameters near line of ring split, in.	
Room temperature	5.186	5.183	5.184
Heated to 120 deg. cent.	5.191	5.188	5.189
Cooled to room temperature	5.186	5.183	5.184
Second heat to 120 deg. cent.	5.191	5.189	5.188
Cooled to room temperature	5.1855	5.183	5.184
Third heat to 120 deg. cent.	5.191	5.1885	5.188
Cooled to room temperature	5.186	5.1835	5.184

It will be seen that the increase of bearing diameters in this case was equal to the expansion of the steel bearing frame, which is natural taking into consideration its rigidity. Since there was not much difference in temperature between the journal and the bearing frame, it can be said that in these tests the clearance was practically without change.

General Procedure Employed in Wiping Tests

After preliminary observations the authors selected the following procedure of tests designed to bring about slight wiping of the lining in a manner convenient for observation. The bearing was "run in" for periods of from one to three days. Now and again during this period the bearing was dismantled for inspection, all high spots being scraped until a definite seat of approximately two inches long formed at the bottom. The load was increased in steps up to 2000 lb., while a constant speed of 300 r.p.m. was maintained. The armature current after running in was quite steady, serving as an indication of the satisfactory condition of the bearing surface. Oil was fed at a rate from 10 to 20 drops per minute (0.5 to 1.0 cc. per min.).

A special oil of light viscosity and containing 10 per cent of lard oil was used with a view to decreasing the effect of a load-carrying viscous film and providing high oiliness of the lubricant.[4] It is worth while noting that an analysis of the oil drained off the

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] The oil was obtained through the courtesy of the United Railways of Baltimore.

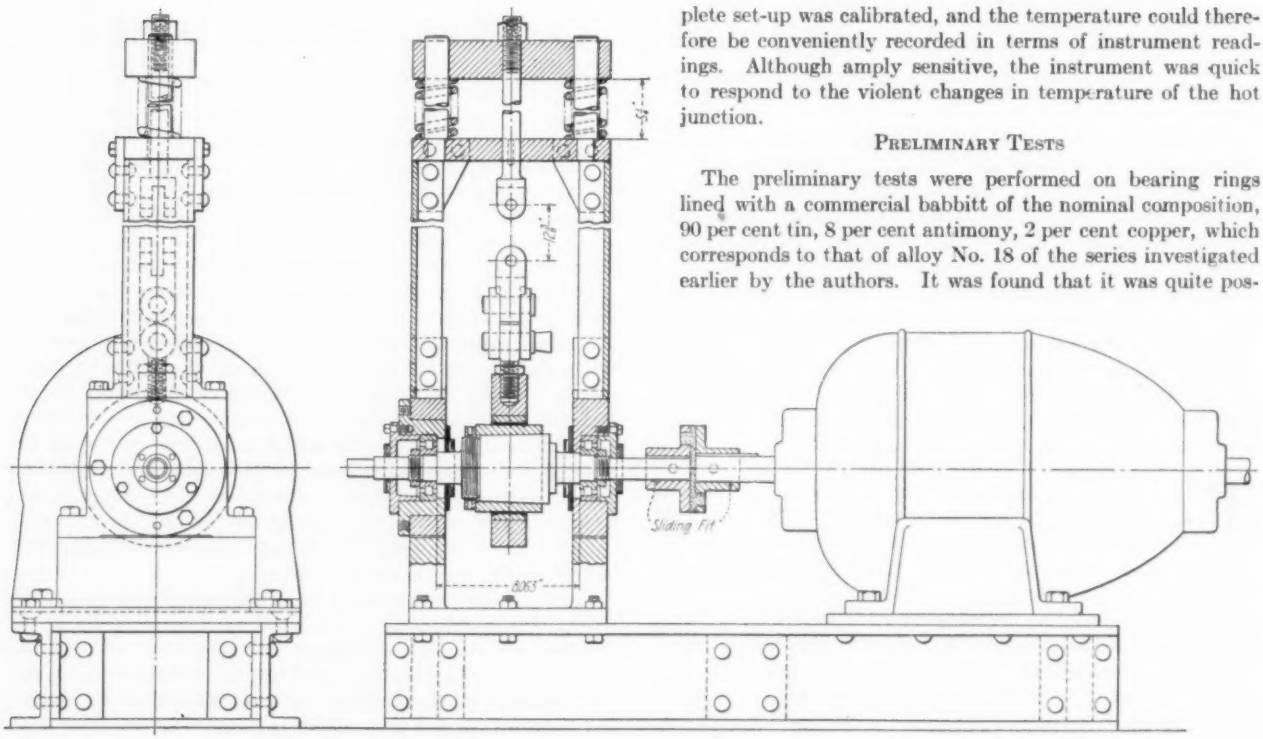

FIG. 1 GENERAL ARRANGEMENT AND DETAILS OF BEARING TESTING MACHINE USED IN TESTS

bearing showed the presence of tin, antimony, and copper in approximately the same proportions as were in the lining, and a considerable amount of iron. "Fibrous material" reported in the oil was due to dust from the air.

With the bearing thus prepared, it was run at 2000 lb. load at 300 r.p.m. until a constant temperature was reached, in the neighborhood of 40 deg. cent. The oil feed was then shut off and the bearing allowed to run further without changing load or speed. After a period of from one to fifteen minutes a sudden increase in friction indicated local seizing with a corresponding increase in temperature. This was measured by a thermocouple which will be discussed later in more detail. The current in the motor field was kept constant during the test, the friction torque being then measured by the armature current. Synchronized readings of torque and temperature were taken every ten seconds and plotted against time. The wide variations observed in the period between the instant when the lubrication was cut off and the first seizure could not be explained by one or another material of the lining, since variations occurred with each material. Apparently it depended on the amount of oil left in the clearance when the needle valve was closed and the condition of the bearing surface. For instance, it was noticed that when linings were run a second time after being once wiped, the bearings could run a considerably longer period without oil. It was not determined whether this was due to oil stored around the thin layer of wiped metal or to the improved bearing surface at the point of wiping.

The thermocouple for measuring the bearing temperature was put in place after the bearing was completely run in, so that it could be located in the close vicinity of journal to lining contact. A copper-constantan couple was used, the cold junction being kept in melting ice, i.e., at 0 deg. cent. The necessity for taking frequent readings during the wiping test proper precluded the use of a potentiometer, and a microammeter of 500 microamperes' range was used in series with the thermocouple. The total resistance of the circuit was approximately 37 ohms. The complete set-up was calibrated, and the temperature could therefore be conveniently recorded in terms of instrument readings. Although amply sensitive, the instrument was quick to respond to the violent changes in temperature of the hot junction.

PRELIMINARY TESTS

The preliminary tests were performed on bearing rings lined with a commercial babbitt of the nominal composition, 90 per cent tin, 8 per cent antimony, 2 per cent copper, which corresponds to that of alloy No. 18 of the series investigated earlier by the authors. It was found that it was quite pos-

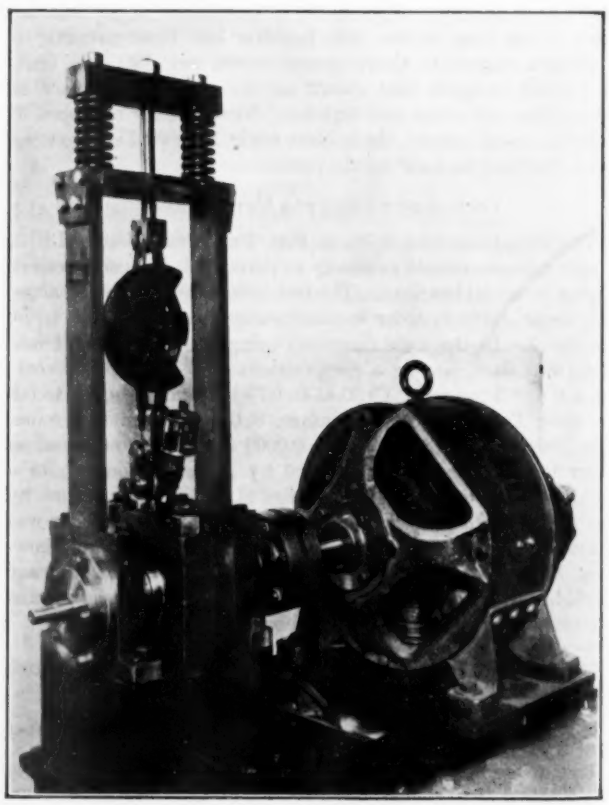

FIG. 2 PHOTOGRAPHIC VIEW OF BEARING TESTING MACHINE SHOWN IN FIG. 1

sible, under the conditions of lubrication described above, to determine the instant of wiping by the sudden increase of friction up to a certain value (800 to 1000 in-lb.). The type of wiping,

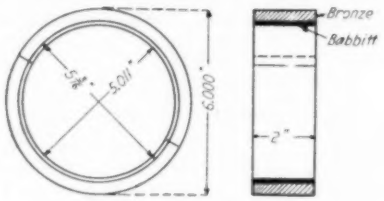

FIG. 3 TEST BEARINGS

common to all failures discussed below, is shown in Fig. 5. The surface layer of metal is seen to be dragged along, forming a thin sheet of babbitt apparently spread over the original surface and fused to it.[5]

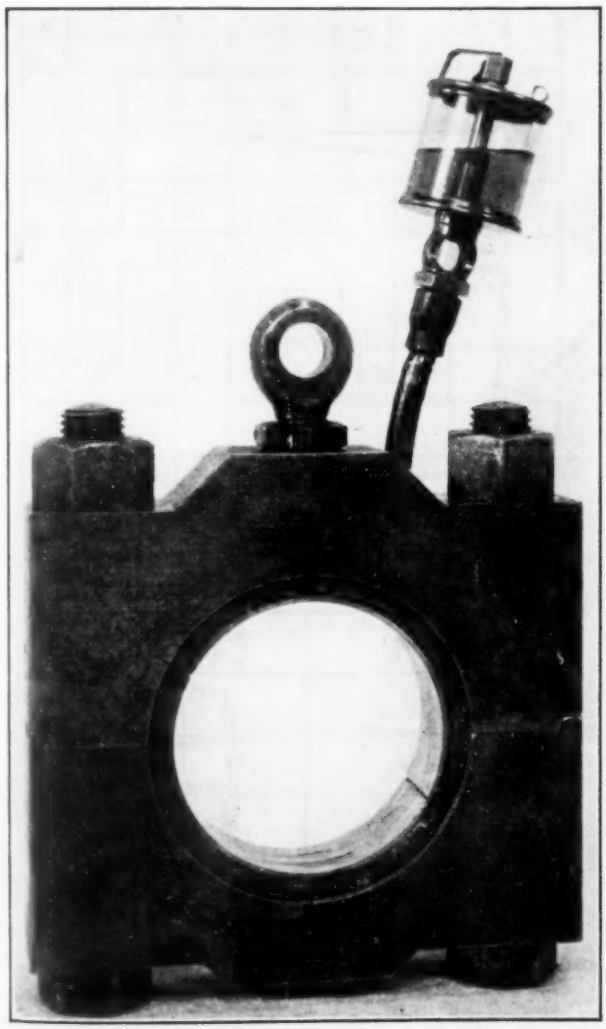

FIG. 4 MOUNTING OF BEARING IN FRAME

The thermocouple used in the earlier tests was placed in the bronze below the babbitt at a distance of approximately 1/16 in. from the rubbing surfaces. Under this condition the temperatures registered when wiping occurred were not higher than 93 deg. cent. and were quite irregular. The change in temperature was not so abrupt as that of torque, and a time lag of the temperature behind the torque was observed. The recorded temperatures in these tests were far below the melting point of the alloys, leading to the belief that a mechanical working of the metal took place. However, when the thermocouple was located nearer the surface of the lining, in the area of actual contact between journal and bearing, higher temperatures were observed. Moreover, a micrographic investigation of the wiped surface did not disclose any signs of cold working, which generally produces a marked orientation of the copper needles in a tin-base babbitt. (For this study copper was deposited electrolytically on the wiped

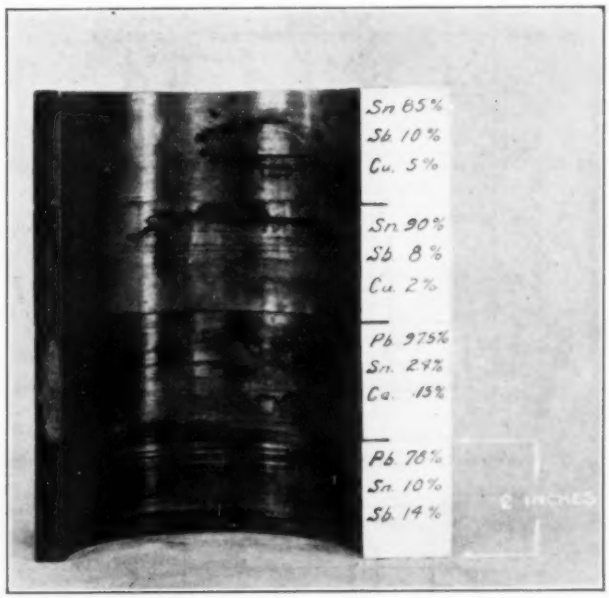

FIG. 5 TYPE OF WIPING EXPERIENCED BY BEARINGS TESTED

portion of the lining and a section across the wiped metal was polished.) An X-ray examination[6] of a tongue of the spread babbitt, which was carefully peeled off, did not show any signs of strain such as might be expected in material mechanically dragged along by the journal.[7] The authors therefore concluded that in

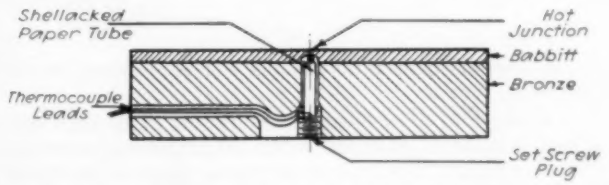

FIG. 6 ARRANGEMENT USED IN MEASURING SKIN TEMPERATURE OF BABBITT LINING

each case the wiped metal must have been melted, and proceeded to obtain a more accurate measurement of the skin temperature of the lining. Fig. 6 shows the arrangement adopted. A very small thermocouple was prepared, the hot junction was mounted in a shellacked paper bushing and the assembly was well cured. The thermocouple was located in a well, drilled to a point within

[5] In most cases a small tongue of metal which could be peeled off the bearing extended beyond the fused portion.

[6] Made by Dr. N. Rashevsky, Research Physicist, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

[7] The authors recognize that annealing of these alloys takes place at room temperature, and that indications of strain might be eliminated on this account.

a few mills of the rubbing surfaces. Positive contact of the junction to the babbitt was obtained by using a small setscrew behind the thermocouple bushing. With this improved thermocouple, sensitive due to its small size, higher skin temperatures were recorded, and the variations of temperature at the area of actual rubbing followed remarkably closely the variations in friction torque. This can be seen in Fig. 7, where a synchronized record of torque and skin temperature is shown for a lining of a special babbitt with a high melting point, which will be discussed further.

Experiments on Wiping

With the improved thermocouple arrangement, linings made of four different bearing metals were tested, following the same procedure as described above. Several linings of each metal were

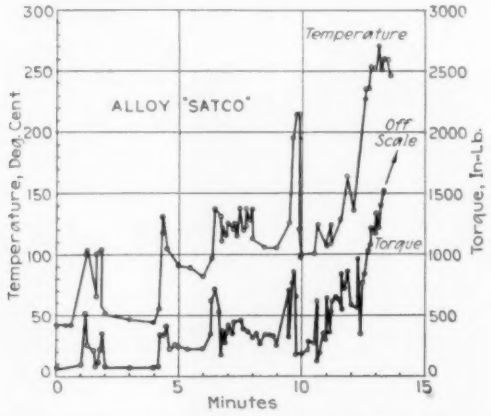

Fig. 7 Synchronized Record of Torque and Skin Temperature

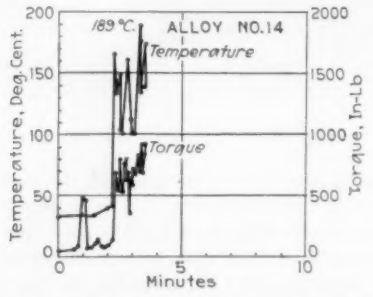

Fig. 8 Typical Record of Friction and Skin Temperature Obtained With a Bearing Lining of No. 14 Alloy

used in order to eliminate the possibility of an occasional error in observation.

(*a*) *Commercial Alloy Westinghouse No. 14.* This alloy has a nominal composition of 85 per cent tin, 10 per cent antimony, and 5 per cent copper. Fig. 8 shows a typical record of the friction and skin temperature in a bearing of this alloy from the instant when the lubrication was cut off until the machine was stopped after gripping occurred. The appearance of this lining can be seen in Fig. 5. It was noticed that the skin temperature at wiping was always between 170 and 180 deg. cent., which was apparently different from the solidus of the alloy or 225 deg. cent. (see p. 15 of the previous paper). However, when a cooling curve was prepared for the lining material, reproduced in Fig. 9, a lower solidus was found—at 180 deg. cent. (see p. 25 of previous paper). This temperature corresponds to the melting point of the lead-tin eutectic; a chemical analysis of the lining actually disclosed the presence of 0.78 per cent of lead. This impurity was the result of tinning the bronze shell prior to pouring the lining, since the shells were tinned with a solder having a composition of Sn, 50 per cent, Pb, 50 per cent.

An interesting check test is shown in Fig. 10. The machine was stopped when lighter gripping and a temperature not higher than 144 deg. cent were reached. When dismantled, the bearing

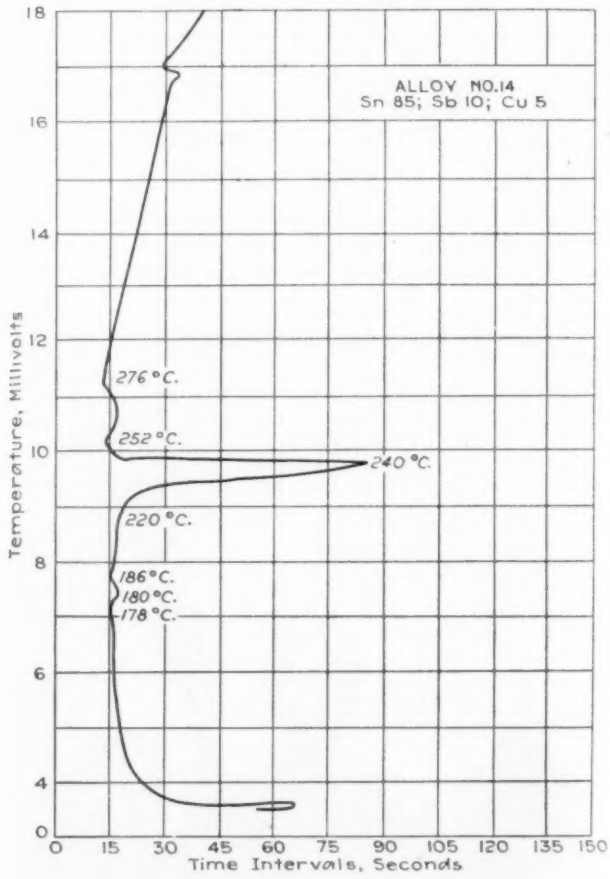

Fig. 9 Cooling Curve for No. 14 Alloy

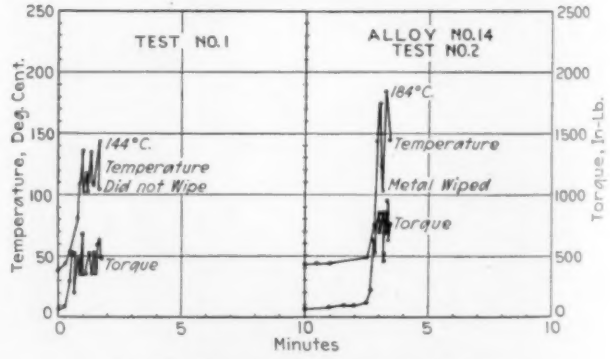

Fig. 10 Check Tests on Alloy No. 14

did not show any signs of wiping. After reassembling the bearing was retested and wiped with a corresponding temperature of 180 deg. cent., approximately.

It was apparent that wiping was a result of the metal reaching its solidus at this temperature. The lead-tin eutectic became liquid and the material "mushy," in which state the upper layer was easily wiped by the journal.

(*b*) *Commercial Alloy Westinghouse No. 60014.* This phe-

nomenon was confirmed when another tin-base alloy was used for a lining. This had nominally 90 per cent tin, 8 per cent antimony, and 2 per cent copper. A typical record of the friction and temperature obtained with a lining of this material is shown in Fig. 11, a photograph of the wiped lining being given in Fig. 5. The wiping again took place at a metal temperature of from 170 to 180 deg. cent., lead being present as a result of the pouring technique. Fig. 12 shows the record of another test made with a lining of alloy No. 60014. This test is of interest because in this case a repeated wiping is easily discernible; one high spot melted away with a resulting drop in friction and in temperature, then a second high spot near-by caught, increased the friction, and melted away. The amount of metal wiped in each case was so small that the molten metal chilled instantaneously. Repeated observations during a number of tests showed that the temperatures of the whole bearing hardly reached 80 deg. cent.

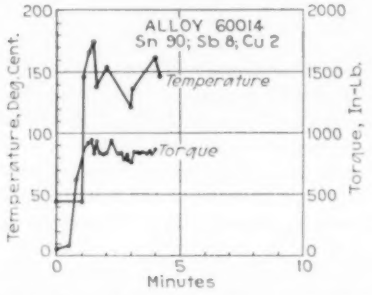

FIG. 11 TYPICAL RECORD OF FRICTION AND SKIN TEMPERATURE OBTAINED WITH A BEARING LINING OF NO. 60014 ALLOY

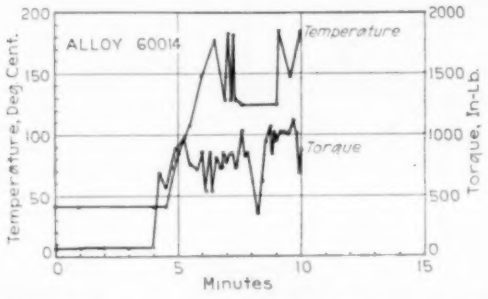

FIG. 12 RECORD OF ANOTHER TEST MADE WITH A LINING OF NO. 60014 ALLOY

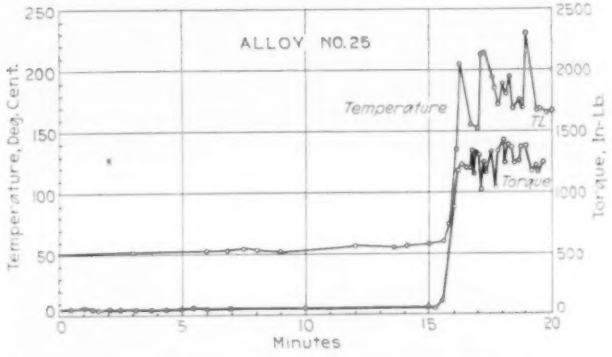

FIG. 14 RECORD OF FRICTION AND SKIN TEMPERATURE FOR BEARING LINED WITH NO. 25 ALLOY

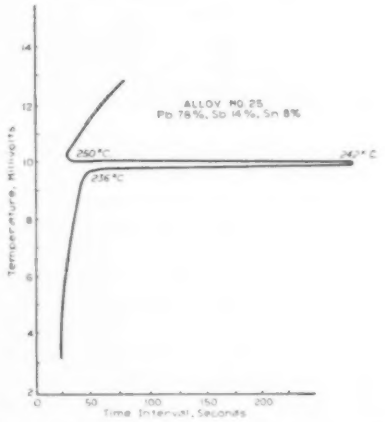

FIG. 15 COOLING CURVE FOR NO. 25 ALLOY

In order to have definite proof that lead in the tinning solder was actually responsible for a wiping temperature lower than the solidus of the Sn 90, Sb 8, Cu 2 alloy, several linings of this metal were prepared using pure tin as a binder between the lining and the shell. Fig. 13 gives the record of the friction and temperature observed when these linings were wiped. Wiping again occurred at 170 to 180 deg. cent. However, a chemical analysis of the lining showed 0.34 per cent of lead present. This came from the commercial

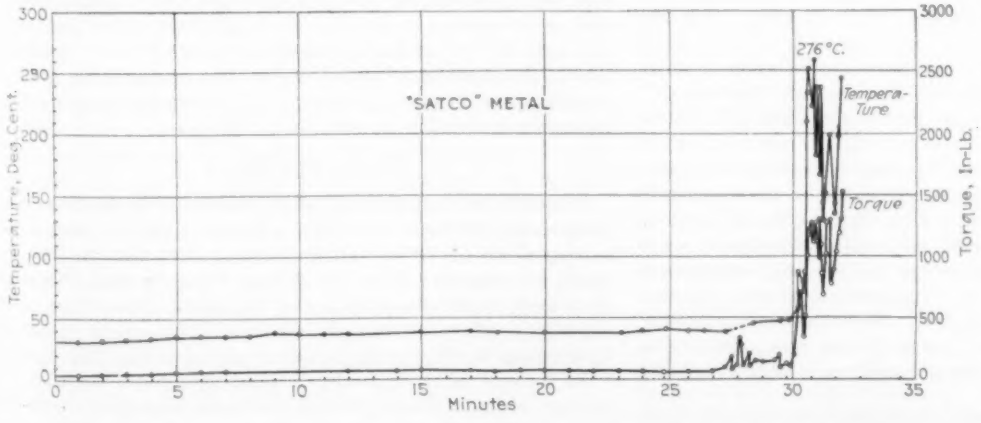

FIG. 16 FRICTION AND TEMPERATURE RECORDS FOR BEARING LINED WITH "SATCO" METAL

tin and antimony used in making the alloy. It was then decided to try alloys quite different from the tin-base babbitts with which this study was particularly concerned.

(*c*) *Commercial Alloy Westinghouse No. 25.* This metal has a nominal composition of 78 per cent lead, 14 per cent antimony, and 8 per cent tin. The same general procedure of testing was followed. One of the wiped bearings lined with the alloy is shown in Fig. 5, while the record of friction and skin temperature for this bearing is given in Fig. 14. The linings wiped at temperatures from 210 to 230 deg. cent. Fig. 15 gives the cooling curve for the No. 25 alloy. The solidus for it is approximately 242 deg. cent., with no lower inversions apparent in the curve. The wider dis-

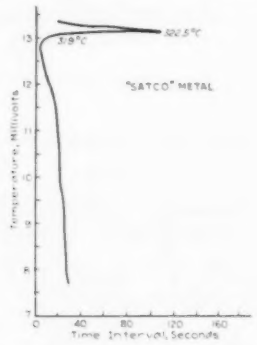

FIG. 17 COOLING CURVE FOR "SATCO" METAL

crepancy between the wiping temperature and the solidus for this metal when compared with the results described above may be easily explained by the fact that the temperatures to be recorded are higher, and the inevitable time lag of the thermocouple is more pronounced.

It is worth while noting the difference in the appearance of the wiped lining in the case of the tin-base and the lead-base metals. The wiping of the latter was found to be appreciably more advanced than with the tin-base metals under the same conditions of testing. It can be explained by the consideration that while in the tin-base babbitts only a minor portion of the babbitt is liquefied at the solidus 180 deg. cent., in the lead-base a considerable fraction of the metal is affected at the temperature 242 deg. cent. Consequently the wiping should be more violent. On the other hand, the mechanical strength of lead-base babbitt at 240 deg. cent. is considerably lower than that of tin-base metal at 180 deg. cent., which is probably the cause of the scored and grooved appearance of the wiped lead-base linings.

This holds true also for the next metal tested, namely,

(*d*) *"Satco" Metal.* This metal was submitted by Mr. C. T. Ripley of the Atchinson, Topeka & Santa Fe Railway. It is one of the metals recently developed containing up to 98 per cent of lead, the necessary strength being secured by addition of small percentages of alkali earth metals. The German "Bahnmetall" is of the same nature. The chemical composition of the submitted sample of Satco was found to be: 97.5 per cent lead, 2.4 per cent tin, 0.15 per cent calcium, 0.07 per cent potassium, and traces of aluminum, barium, magnesium, and sodium. Its strength is approximately the same as that of the 90 Sn, 8 Sb, 2 Cu alloy. A photograph of one of the bearings lined with this material is given in Fig. 5, the corresponding friction and temperature records being shown in Fig. 16. The skin temperature recorded at wiping was 270 to 290 deg. cent. Fig. 17 shows the cooling curve for this metal.[8] The solidus is 320 deg. cent., and no discontinuities in the cooling curve at lower temperatures could be found. The discrepancy between wiping temperature and solidus was caused probably by the time lag of the thermocouple.

The length of the time between the stoppage of lubrication and wiping (30 min.) is accidental. Other linings of the same material wiped shortly after the needle valve was closed. As mentioned before, this time depended mostly on the condition of the bearing surface.

DISCUSSION OF RESULTS

In the authors' estimation the reported series of tests, of which typical examples were shown above, proves quite definitely that rise of temperature right at the journal is essential for wiping. It appears that in so far as tin-base babbitts are concerned, the unavoidable lead content in commercial tin and antimony causes all metals of this type to wipe at the same temperature of 180 deg. cent. However, this wiping is only slight and generally

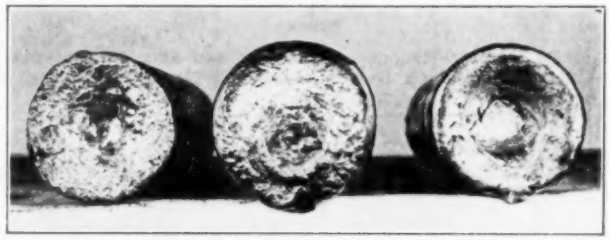

FIG. 18 TOP VIEW OF INGOTS CAST FROM TIN-BASE BABBITTS

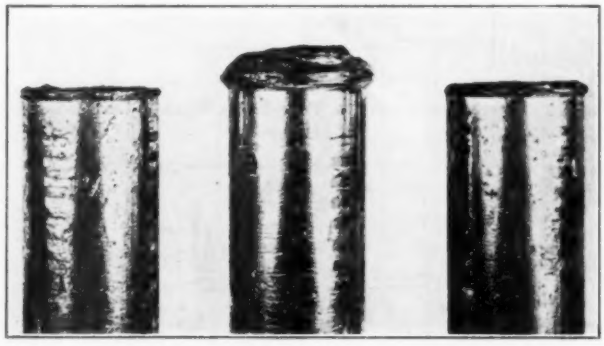

FIG. 19 SIDE VIEW OF INGOTS CAST FROM TIN-BASE BABBITTS

does not exclude the possibility of subsequent successful service of the bearing, provided the conditions which led to the wiping are eliminated (lack of lubrication, misalignment, etc.). A tin-base babbitt should therefore be selected for a particular application on the basis of its mechanical strength and ease of pouring. The authors are therefore augmenting the data given in the first part of the study by recording further observations made during the casting of the various alloys of this series and data on the resistance of the alloys to plastic deformation.

CASTING PHENOMENA

When the castings of the 25 alloys referred to in the first part of this study were set up in order, it was noted that all those containing about ½ per cent of copper, no matter what their antimony content, were characterized by a relatively deep pipe and by a lustrous surface at the top of the ingot. The surface was crinkled, but free from any granulation. There was no evidence of shrinkage cracks (see the left-hand casting of Fig. 18).

In the case of those castings containing about 1 per cent of copper, the upper surface protruded from the mold (see the middle casting of Fig. 19). The surface was lustrous but was character-

[8] Prepared by Dr. F. R. Hensel, Research Metallurgist, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

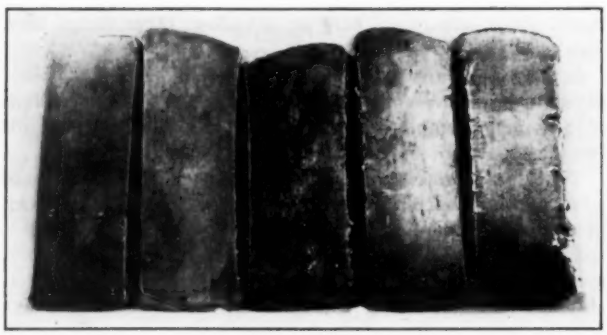

Fig. 20—Samples 1–5

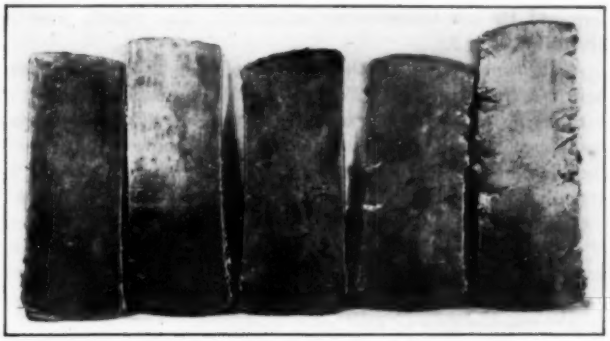

Fig. 22—Samples 11–15

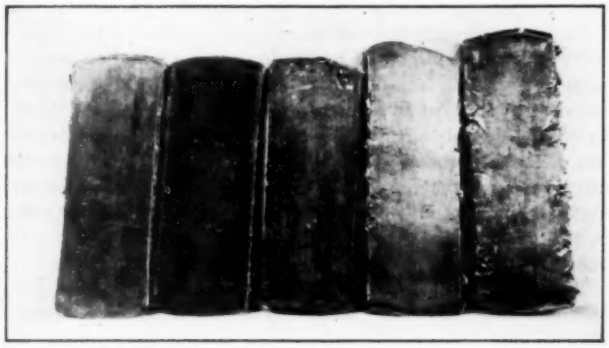

Fig. 21—Samples 6–10

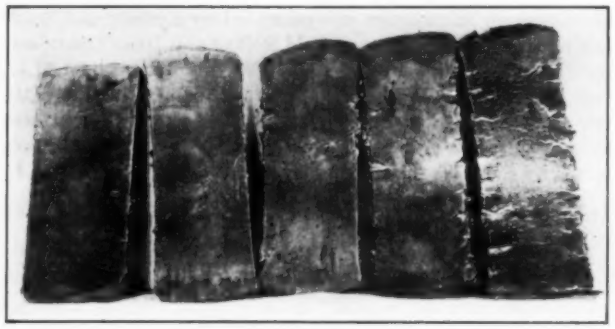

Fig. 23—Samples 16–20

ized by numerous excrescences. These swellings were filled with gas expelled from the alloy during its solidification.

Those castings containing 2, 4, and 8 per cent of copper, respectively, no matter what their content of antimony, were also characterized by a pipe, but this pipe was relatively shallow and at its apex was, in most cases, marked by a shrinkage crack (see the right-hand casting in Fig. 19). The surfaces of the castings were less lustrous than those of the castings already described, this lack of luster being due in large measure to granulation of the surfaces occasioned, no doubt, by the presence of crystals of the tin-copper compound, CuSn.

Fig. 24—Samples 21–25

FIGS. 20–24 APPEARANCE OF SAMPLES AT CONCLUSION OF ROLLING OPERATIONS

The peculiar character of the castings containing about 1 per cent of copper appears to the authors to be due to the conditions of freezing of these alloys. In the case of those alloys containing either less and more than 1 per cent of copper, freezing is in progress over a range of temperature, and during the time that the alloy is in process of solidification, gases present in the alloy can escape without hindrance. In the case of the alloys containing about 1 per cent of copper, the freezing range is relatively narrow and solidification of the metal in the mold is rapid. The gases escaping from the casting are thus entrapped in the upper part of the mold and make their presence evident by the formation of blowholes and bubbles near or in the upper surface of the casting.

THE EFFECT OF COLD WORK

A number of references to the effect of cold work on alloys of this type have appeared during the past few years. Thompson and Orme (*Jl. Inst. Met.*, vol. 22 (1919), p. 203), for example, remark that the rolling of Britannia metal "presents very little difficulty. An ingot $^3/_4$ in. thick can be reduced to $^1/_{16}$ in. in about a dozen passes, which treatment results in little or no hardening." No specific alloy is referred to in their remarks. Greaves (*Jl. Inst. Met.*, vol. 22 (1919), p. 213), in discussing their paper, showed that rolling progressively softened these alloys but that "aging" tended to restore their hardness. His tests were made on three alloys of the following compositions, cast in warm molds into ingots $1^1/_2$ in. square.

Ingot number	1	2	3
Copper, per cent	nil	0.81	1.5
Antimony, per cent		5.0 to 5.5	

Hardness tests were made with a 10-mm. ball under a load of 500 kg. for one minute. The ingots were rolled to 0.8 in. thick and hardness tests again made on the surface, and the alloy was found in each case to be softer. Rolling was continued without annealing to 0.6 in. thick and a further set of hardness tests made,

TABLE 2 EFFECT OF COLD WORK ON HARDNESS OF BRITANNIA METAL (DIAMETER OF IMPRESSION IN MM.)

Ingot number	1	2	3
As cast	6.29	5.64	5.23
Rolled to 0.8 in., 20 min. after rolling	7.03	5.85	5.99
Rolled to 0.6 in.; 20 min. after rolling	7.40	6.70	7.04
Rolled to 0.6 in.; three days after rolling	..	6.68	6.90
Rolled to 0.6 in.; after 1 hr. at 100 deg. cent	7.24	6.47	6.64
Rolled to 0.6 in.; after 1 hr. at 200 deg. cent	6.37	5.87	5.75

followed by low-temperature annealing. The results were as given in Table 2.

At the same meeting of the Institute of Metals, Fry and Rosenhain (*Jl. Inst. Met.*, vol. 22 (1919), p. 219) discussed the effect of hammering on the hardness and structure of a typical bearing metal cast under a variety of conditions and showed very clearly that hammering softened the alloy, while hammering followed by annealing at 100 deg. cent. for 16 hours resulted in quite appreciable softening. Fry and Rosenhain also showed the importance of structure upon the resistance of these alloys to deformation, noting that the fine-grained ingots stood the hammering comparatively well, whereas the coarse-grained samples cracked and broke after but a small amount of hammering.

At the Philadelphia (October, 1928) meeting of the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers, a considerable contribution to our knowledge on this subject was presented by Egeberg and Smith in a paper entitled, "Effect of Cold Rolling and Heat Treatments on Physical Properties of Britannia Metal" (Trans. A.I.M.E., Inst. Metals Div., 1929, p. 373). The approximate analysis of the materials investigated by them was 91 per cent tin, 7 per cent antimony, and 2 per cent copper. The results which were obtained by them are shown in Table 3.

TABLE 3 EFFECT OF HAMMERING ON HARDNESS OF TIN-BASE BABBITT

	Initial state	After boiling in water 30 min.	After heating at 300 deg. fahr. 90 min.	After heating at 400 deg. fahr. 45 min.	After heating at 440 deg. fahr. 30 min.
	Brinell hardness

Cold rolled to 1/32 in.	[a]	[a]	[a]	[a]	[a]

[a] Too thin for Brinell test.

Here again confirmation of the softening effect of cold work on these high-tin alloys was obtained. The further interesting fact was elicited in the discussion of this paper by one of the present authors (O. W. E.) that the hardening of these alloys due to heating after cold rolling (cf. Table 2) is a characteristic only of material which has been highly deformed—in the case of the 91 per cent tin, 7 per cent antimony, and 2 per cent copper alloy reduced one-half to two-thirds or more in thickness by cold rolling. When the amount of deformation is less than about 50 per cent, then further softening occurs on annealing, other things being equal.

TABLE 4 NOMINAL COMPOSITIONS OF ALLOYS TESTED IN ROLLING EXPERIMENTS

25	82	10	8

In the present investigation the effect of cold work on 25 alloys of the tin–antimony–copper system has been studied. The alloys' of the nominal compositions given in Table 4, were machined into test pieces, 1 1/2 in. long, 1 in. wide, and 1/2 in. thick.

The initial hardness of each sample, as machined, was taken on a baby Brinell machine, using a 1/16-in. ball. But the variation in the size of the impressions was so small that it was decided to use an 1/8-in. ball and no load in the lever arm on the Rockwell machine. The results obtained on the Rockwell tester are probably not very accurate as to the absolute hardness of the alloys, but they show the general trend of the effects of cold rolling quite well. After each pass through the rolls the samples were allowed to stand about four hours before testing in order to make sure they were always tested at room temperatures.

Each pass through the rolls caused a reduction of 5 per cent or 0.025 in. The depth of the impression of the 1/8-in. ball was calculated to be 1/64 in., and it was assumed the alloys could be rolled to twelve times the depth of the impression, or 3/16 in., without noticeably affecting the results. On this assumption the test pieces were rolled to 0.175 in. Every sample was given the full reduction on each pass, no attempt being made to stop cracking by trimming the samples after rolling. All pieces were rolled to the finished size except one (No. 25), which broke up completely on the twelfth pass.

Table 5 gives data as to the compositions of the alloys, their hardness before and after rolling, and the condition of the samples after rolling.

TABLE 5 INITIAL AND FINAL HARDNESS OF ROLLED BABBITTS

Sample no.	Per cent Cu	Per cent Sb	Hardness before rolling	Hardness after rolling	Condition after rolling
1	0.5	2	0.7	10.0	No cracks
2	0.5	4	7.9	—0.7	No cracks
3	0.5	6	18.8	—5.0	No cracks
4	0.5	8	25.8	0.0	Small cracks
5	0.5	10	40.0	4.0	Few large cracks

8	1	6	33.9	10.0	No cracks
9	1	8	40.5	14.5	Few large cracks
10	1	10	52.1	9.0	Few large cracks
11	2	2	32.7	26.2	No cracks
12	2	4	39.2	12.7	No cracks
13	2	6	44.4	9.7	No cracks
14	2	8	49.8	17.8	Few large cracks
15	2	10	61.9	18.0	Large deep cracks
16	4	2	46.8	23.3	No cracks
17	4	4	49.0	18.0	No cracks
18	4	6	55.6	13.0	Small cracks
19	4	8	57.1	12.0	Large cracks
20	4	10	63.9	15.0	Large cracks
21	8	2	51.0	17.5	Very few cracks
22	8	4	50.0	15.0	Very few cracks
23	8	6	51.6	14.7	Few large cracks
24	8	8	58.2	12.5	Large deep cracks
25	8	10	68.7	—9.0 [a]	Broken

[a] No. 25 completely broken on twelfth pass. Hardness after eleventh pass is quoted.

Figs. 20 to 24 show the appearance of the samples at the conclusion of the rolling operations. The rectangular section missing in the 10 per cent antimony sample of Fig. 24 was used as a specimen for microscopic examination (see below).

The hardness numbers observed at the conclusion of each of the passes are given in Table 6.

The values given in Table 5 have been used in the preparation of the curves shown in Figs. 25, 26, 27, 28, and 29. A study of these curves elicits two outstanding facts:

1 That, no matter what their content of copper, the alloys of low antimony content increase in hardness during the first stages of reduction, later decreasing in hardness as deformation is continued. In this connection it is of interest to note that the initially soft alloys retain their hardness with increasing deforma-

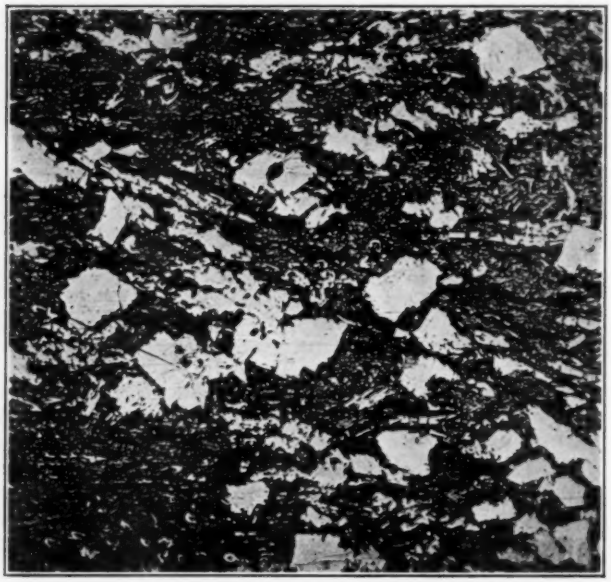

FIG. 30 MICROSTRUCTURE OF SAMPLE CUT FROM ALLOY NO. 25 AFTER HAVING BEEN REDUCED 65 PER CENT IN THICKNESS BY ROLLING. MAGNIFICATION 150×

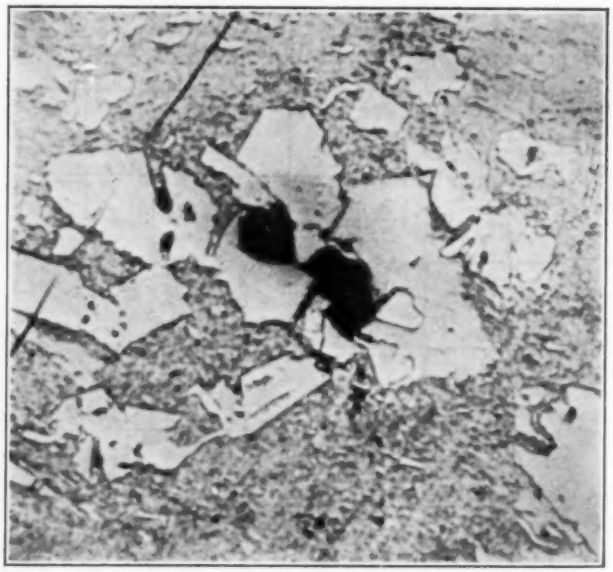

FIG. 31 PHOTOMICROGRAPH OF UNETCHED SECTION OF SAMPLE ILLUSTRATED IN FIG. 30, SHOWING EVIDENCE OF FORMATION OF CAVITIES

tion more completely than the initially hard, so that after reduction to 0.175 in. the initially soft alloys have in many cases become harder than the initially hard.

2 That, no matter what their content of copper, the alloys of high antimony content (8 per cent and 10 per cent) *tend* to decrease in hardness continuously as they are reduced in thickness by rolling.

MICROSTRUCTURE—DENSITY

The effect of plastic deformation on the microstructure of these alloys has been referred to by Fry and Rosenhain (loc. cit.), who have shown that hammering had the effect of breaking both the cubes of tin-antimony compound and the needles of CuSn. Rolling has much the same effect as hammering, as may be seen by reference to Fig. 30, which shows the microstructure of the sample cut from alloy No. 25 after it had been reduced 65 per cent in thickness by rolling. It is of interest also to note the tendency of the CuSn needles to orient themselves in the direction of rolling. In this photomicrograph, evidence of the formation of cavities, both in the matrix of the alloy and within the shattered cubes of the tin-antimony compound, is forthcoming. Confirmation of this effect of deformation is given in Fig. 31, which is a photomicrograph of an unetched section of this alloy at a magnification of 500 diameters. The cavities in the vicinity of a shattered cube of SnSb are very clearly defined in this section.

Whether the decrease in hardness occasioned by deformation can be ascribed in all cases to the disruption of the structure is open to question in view of the experience of Egeberg and Smith, who have shown that the annealing of cold-rolled Britannia metal (91 per cent Sn, 7 per cent Sb, 2 per cent Cu) causes it to increase in hardness quite appreciably, though, be it noted, never to recover its original resistance to deformation. The authors are of

the opinion that at least some of the loss in hardness can be ascribed to the formation of cavities within the material, particularly in the case of such material as contains cubes of the tin-antimony constituent.

Confirmation of the formation of cavities within the material is obtained from density measurement. The fact that deformation reduces the density of these alloys has been referred to by Thompson and Orme (loc. cit.) in their reply to the discussion of their paper. They quote Dr. Carl Kamarsh as having shown that rolling lowers the specific gravity of Britannia metal from 7.361 to 7.339. The authors' experiments on this phase of the subject were made on two pieces (numbered 1 and 2) $^1/_2$ in. thick and about 1 in. square, taken from an alloy containing approximately 94 per cent tin and 6 per cent antimony. The specific gravity of these was found to be 7.402 and 7.405, respectively, thus showing that the method used for the determination of specific gravity was correct to a small integer in the third decimal place. The pieces were then rolled to the same thickness as the other samples, namely, 0.175 in. Piece No. 2 was taken down in regular steps of 0.025 in. per pass. No attempt was made to regulate the number of passes to which No. 1 was subjected, it being merely used as a gage for No. 2. In all probability No. 1 received three times as many passes as No. 2, and the average reduction per pass was one-third that of No. 2. When the specific gravity was again taken, No. 1 was found to have decreased from 7.405 to 7.053, and No. 2 from 7.402 to 7.092.

Constitution of the Tin-Antimony-Copper System

In both of the authors' papers the cube- and needle-shaped constituents of these alloys have been referred to as SnSb and CuSn, respectively. In referring to these constituents in this way they have followed the lead of Campbell (Proc. Am. Soc. Test. Matls., vol. 13 (1913), p. 630) and of Bonzack (*Zeit. für Metallkunde*, vol. 19 (1927), p. 109), who are in apparent agreement as to the nature of these phases. The authors, while admitting the likelihood that in these alloys as cast the cubes are essentially of the compound SnSb, are not prepared to accept without comment the view that the needles are of the compound CuSn, seeing that the existence of this compound has still to be confirmed.

Both Shepherd and Blough (*Jl. Phys. Chem.*, vol. 10 (1906), p. 630) and Haughton (*Jl. Inst. Met.*, vol. 25 (1921), p. 309) offer proof that these needle-shaped crystallites consist of a solid solution of variable composition to which they have applied the symbol ϵ (epsilon). Nevertheless, while the authors are of opinion that the experimental methods adopted by Shepherd and Blough and by Haughton in their investigation of the copper–tin system are on the whole superior to those used by Ishiwara (*Jl. Inst. Met.*, vol. 31 (1924), p. 315), the latter's opinion that the epsilon constituent is the compound CuSn cannot be lightly dismissed, particularly when the cast alloys of this system are under consideration. In brief, the authors believe that the needles in these alloys as cast are of the compound CuSn, but in these alloys in a state of equilibrium are of a solid solution (ϵ).

Discussion

E. I. Larsen.[9] It may be interesting to note the effect of aging on the cold-rolled metals referred to in this paper. Subsequent to rolling, the pieces were aged for two months at room temperature (approximately 24 deg. cent.), after which hardness measurements were made. The pieces were then given an accelerated aging in boiling water (97 deg. cent.), and the hardness was again measured. Following the aforementioned treatment, the samples were further aged at room temperature for a period of six months before again measuring the hardness. Curves were drawn similar to those of the authors in which the antimony percentages in the various copper groups were plotted against hardness. The variations in hardness were found to be fairly small, the maximum change being approximately 20 points (Rockwell B hardness scale, $^1/_8$-in. ball, no load) or about 30 per cent of the total change due to rolling. The maximum change occurred during the two months after rolling. The hardness of the alloys containing 4 and 8 per cent of copper increased, while the hardness of those containing less than 4 per cent decreased.

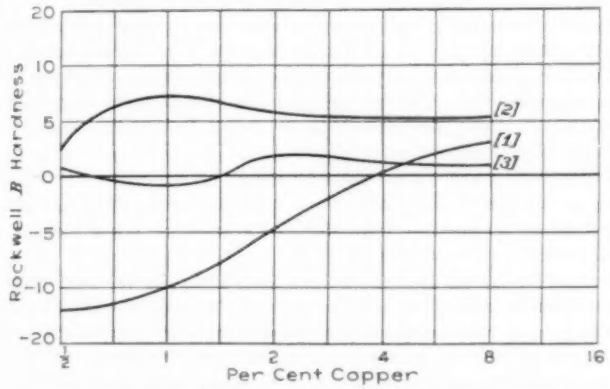

Fig. 32 Change of Hardness During Aging Periods
(Aged [1] for two months at room temperatures; then [2] for eight hours at 95 to 100 deg. cent.; then [3] for six months at room temperature.)

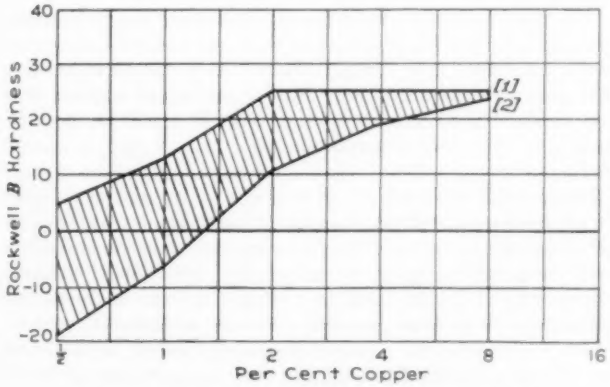

Fig. 33 Hardness Range in Groups After Aging
(Top curve [1], maximum hardness; bottom curve [2], minimum hardness.)

Now if the curves of each copper group are averaged, it will be noted that in the case of the alloys containing less than 4 per cent copper the change in hardness resulting from aging for two months at room temperature is inversely proportional to the copper content; while for alloys containing 4 per cent or more of copper the change in hardness is directly proportional to the copper content. (See curve 1, Fig. 32.) All the alloys became slightly harder during the eight hours' aging in boiling water. (See curve 2, Fig. 32.) The subsequent aging for six months produced little change in the various groups. (See curve 3, Fig. 32.) It was noted, however, that after the aging treatment the hardness of the several alloys in the group containing 0.5 per cent copper varied over a range of 25 Rockwell B points; whereas if the copper content is increased to 8 per cent, the range of hardness has decreased to approximately two Rockwell B points. (See Fig. 33.)

The foregoing results may be of little practical value, but they are most interesting from a theoretical point of view. These data seem to indicate that copper is the major factor in promot-

[9] Research Laboratory, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

ing age-hardening in alloys of this type. However, further work is necessary before definite conclusions can be drawn.

H. A. S. HOWARTH.[10] This contribution on tin-base bearing metals is an important addition to the literature on the nature and causes of bearing failures. Although the authors now discuss their failure in the absence of a lubricant, it is hoped that they will continue their study further and show the nature of failures that occur in the presence of lubricants. The oil may be overloaded with gritty matter or it may be used in the presence of electric potential difference between the bearing surfaces.

The writer is glad to have the suggestion that the presence of so small an amount of lead as 0.34 per cent in a tin-base babbitt makes it sensitive to overheating and more liable to failure in the absence of oil. Occasionally the question of lead contamination arises in the purchase of babbitt metal, bought by this company in large quantities on specification.

Prevention of contamination of babbitt in the shop is assisted by use of babbitt for tinning the bearing surfaces and by the use of babbitt heads on soft hammers. Lead is kept out of this factory as far as practicable.

An examination of Figs. 25 to 29 leads one to the conclusion that peening would be less harmful for compositions whose hardness is least changed thereby if the peening were done merely to tighten the hold of the anchors. If, however, peening is resorted to for hardening the surface, the composition must be chosen accordingly. However, this company disapproves of peening and uses a composition that lies between those illustrated by Figs. 28 and 29. This practice therefore appears rational.

From the authors' remarks about "running in" the journal and bearing before testing, it is evident that they realize the influence of journal finish upon bearing failure. It would be interesting if they would follow this phase further and report whether they can obtain a journal material and finish that will be most reluctant to seize the bearing metal.

The writer once tried to produce seizure by pressing a small block of babbitt, held in a tool post of a boring mill, against the finished surface of a thrust-bearing runner made of cast iron, but could not get them to seize. This was only a crude and unrecorded experiment, but it led to the belief that "finish" was very important and that persistence of change in shape of the runner surface due to operating temperatures was a factor not to be overlooked. Hence, tests should be conducted with models that adequately resemble the bearings to the improvement of which the test results are to be applied.

For the foregoing reason it is believed that the authors should have used a shaft whose journal would not trap the heat so readily. A sleeve, when used as a journal, will heat and expand away from the shaft. As soon as this separation takes place the heat is trapped and the sleeve will expand rapidly and may bring about failure sooner than it would have occurred if the journal had been integral with the shaft. With an integral journal the test results might be more consistent.

The writer would like to ask the authors why they chose to publish Fig. 16 when it was not representative of the results of several tests of Satco metal? They state in the text that "the length of time, 30 minutes, is accidental. Other linings of same material wiped shortly after the needle valve was closed." They then add, "As mentioned before, this time depended mostly on the condition of the bearing surface." Do they mean that this is true of every time chart shown? If that is so, it would appear that they should have charted the influence of finish upon the time before failure for each pair of materials used. They might also have shown the influence of the character of the lubricant upon the time. On the whole it appears that this series of experiments should be looked upon as only begun, and the present report as incomplete and inconclusive.

C. H. BIERBAUM.[11] The entire test as made may be termed a destructive test, both as regards design and operation; that is, the material was tested to destruction and not within practical working limits.

In all bearing testing, not only the bearing material, but the shaft or journal as well, should be studied microscopically and metallographically. The chemical composition of the bearing sleeve is given; however, it does not mention whether in a heat-treated condition or not, nor does it give the conditions of the surface of the sleeve after the test was completed. The report, however, does state that "a considerable amount of iron" was found in the drained-off oil. What does this mean? Was the sleeve subjected to a polishing or roughing effect? Since the best bearing conditions require that a mutual polishing effect should exist between the bearing and the journal, the resulting or final condition of the surface of the journal is just as important as that of the bearing surfaces.

The entire work done on the cold rolling and cold working of the material, as shown in this paper, does not seem to the writer to have any relation to bearing testing whatsoever, in that all bearing alloys should be left, as near as possible, in their natural crystallized form, without having any work done upon them to crush or break up the hard bearing crystals. Babbitts should never be peened or cold-worked to the extent of either crushing or breaking up the copper-tin or the tin-antimony crystals. The preferred condition for the application of babbitt is of course to sweat the same upon a backing, as was done in the experiments under consideration. Neither the temperature at which the molten babbitt was poured nor the temperature of the brass backing at the time of pouring is given in the report; therefore, the rate of solidifying or cooling of the molten babbitt and its consequent crystal structure is left entirely a matter of conjecture. This latter condition has a material effect upon the resulting bearing value. Best of all would have been to have had full photomicrographs and a complete metallographic study of the same.

The desirability of having the crystalline structure in addition to the chemical composition is shown very strikingly and conclusively in the remarkable babbitt tests made by Holm Graefe in the Metal Testing Laboratories of the Siemens-Schuckert-Werke A.-G., Berlin, entitled, "Der Einfluss der Giesztemperatur auf die Laufeigenschaften von Lagermetall," as reported in *Maschinenbau* of October 20, 1927. These tests were all made within the limit of practical working conditions and accordingly cannot be classified as destructive tests; they are therefore of direct practical application.

Graefe shows very interestingly the bearing value and performance of several babbitts. He shows that this bearing value of the different linings is distinctly improved by pouring the same at a high temperature on preheated shells; that is, having the cooling or solidifying of the babbitt proceed at a slow rate and thus resulting in a coarse grain. Graefe found that the performance in every case is superior where the crystallization is coarse and when the hard bearing crystals are largest. In a babbitt containing both copper and tin, of the class of babbitts which Messrs. Karelitz and Ellis have tested, the tin-copper epsilon crystal is harder than the tin-antimony crystal.

The photomicrograph (Fig. 34) shows this epsilon crystal in its entirety. It also shows within its border a darker formation having the chemical composition of $SnCu_3$. This inner or darker crystal has not sufficient time to form under severe chilling condi-

[10] Vice-President and General Manager, Kingsbury Machine Works, Philadelphia, Pa. Mem. A.S.M.E.

[11] Vice-President and Consulting Engineer, Lumen Bearing Company, Buffalo, N. Y. Life Mem. A.S.M.E.

tions, but it does form when slowly cooling, and the slower the babbitt cools, the larger the amount of this inner crystal. Now, the fact is that the darker inner crystal is the hardest tin-copper crystal known; it is appreciably harder than any crystal found in the phosphor bronzes. By the slower cooling the increased amount of this hard crystal in the babbitt may produce very favorable results, provided the mating journal is hard enough and also possesses a sufficient degree of microscopic homogeneity, in order that this darker inner crystal does not become distinctively abrasive to the journal. It seems that Graefe, in his conclusions, did not appreciate the value or hardness of this inner crystal, in that he attributes all the improvement to slow cooling

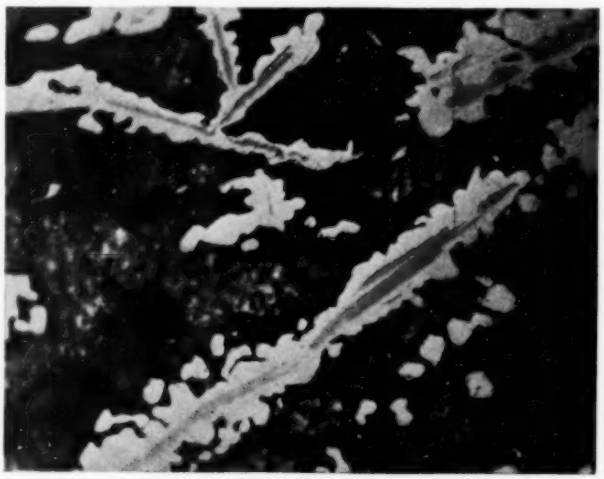

FIG. 34 PHOTOMICROGRAPH OF EPSILON CRYSTAL

and the resultant coarse grain structure. It should also be added that the physical properties of Graefe's test journal were such that it gave him the full benefit of these harder crystals.

The microhardness of the $SnCu_3$ phase, the inner dark crystal, is 1006, whereas that of the epsilon crystal, which is not of a definite chemical composition, has a microhardness near 600 or 700, even less than that of the hard delta crystal in the phosphor bronzes.[12] It is entirely possible that the variation in the amount of this hardest crystal and its behavior upon the journal accounted for some of the variable behavior of the bearings in question, as found by Messrs. Karelitz and Ellis, in that a variable amount of the residual lubricant upon the journal can readily be accounted for by a variable amount of this hard crystal.

The tooling or finishing of bearing surfaces likewise has a very important bearing upon their behavior. The final tooling should be done with very light cuts, at a high speed and with very sharp tools, in order to destroy the natural crystallization to the least possible depth. Experience on a very large scale has shown that in the finishing of sweated-in babbitt bearings, if cut with a very sharp diamond or tungsten-carbide tool at an extremely high speed, surfaces can be produced that approach very closely to a "run-in" surface, equal to those that would require weeks, if not months, by the running-in process. If the finishing is done with a few very fine cuts, and having the last cut, say, less than 0.001 in., a babbitt bearing surface can be produced with the hard bearing crystals immediately upon and flush with these finished surfaces, a condition always found in a perfect "run-in" state. A bearing surface is not completely run-in until all of the hardest crystals are flush with the bearing surface.

During the last thirty-five or forty years an enormous amount of bearing testing has been done by individuals and private corporations. If all the facts could be assembled, the aggregate amount of work done would be enormous; on the other hand, the small amount of positive information obtained is far more astounding. The answer to all of this is self-evident: tests have been made in a destructive manner; investigators hoped to obtain, by a few hours' test, actual bearing values. By strictly destructive bearing testing so far "no one has gotten anywhere and all have gotten nowhere."

A. NADAI.[13] The paper is very valuable as the authors endeavored to investigate, not only the physical conditions under which a soft bearing metal wipes, but also to determine the mechanism of wiping itself in a babbitt. In this respect the writer would like to support the general proceeding of the authors in their interesting tests and especially the fact that they tried to exaggerate certain conditions in their tests. They succeeded by this method in finding the important result that wiping in a bearing means melting of a component in the babbitt-metal lining.

The writer would be interested to know more about the mechanical conditions which are present in the small portion of the surface of a bearing in which the shaft actually wipes on the bearing shell. The normal pressure at the points of contact will be certainly comparatively large. He would like to ask if the authors have perhaps investigated also the average value of the tangential stress component in the surface of contact, because the actual conditions of wear may perhaps be determined more exactly if both components, the normal and the tangential, at the points of contact, could be predicted. It is perhaps possible that also the tangential component may have a greater effect on the wiping.

AUTHORS' CLOSURE

With reference to Mr. Howarth's remarks, the authors' intention was to emphasize the fact that independently of the conditions of finish and the time necessary to produce the first seizure of the shaft, the temperature registered by the thermocouple near the skin layer of babbitt was a temperature characteristic of the babbitt material. It is very important to note that this temperature was registered without any control of oil conditions or particular care to produce uniform finish. The same refers in part to Mr. Bierbaum's discussion. A record of all the details of composition and condition of the shaft would obscure the issue rather than be useful in this instance. The temperature of pouring was not controlled beyond the ordinary shop process control. A thorough study of the finer points of influence of the finish and oil on the time of running between lubrication stoppage and first seizure and the influence of the pouring temperature, if any, on the wiping temperature would, no doubt, be very interesting.

The results of the tests on cold rolling are reported as a continuation of the measurements of strength of the tin-copper-antimony series given in the first part of the paper. It is true that we do not possess at present any reliable simple test which would prove or disprove the suitability of a babbitt as a bearing metal. We must therefore go through all the "destructive" tests and by comparing with actual experience come to some conclusions. Now, however, we are in a position to add the wiping test to the tests dealing with mechanical strength only. It is true that the cold-rolling test is no more justified than a Brinell test, in so far as it does not at all represent the true working conditions of a bearing metal. However, in such applications as internal-combustion engines, the ductility of the babbitt is rather important, and in some instances this property may serve as a guide in the choice of the proper material.

Present Practice in the Use of Cutting Fluids[1]

Progress Report No. 2 of the Sub-Committee on Cutting Fluids[2] of the A.S.M.E. Special Research Committee on Cutting of Metals

COMPILED BY S. A. McKEE,[3] WASHINGTON, D. C.

This report is an attempt to indicate, in so far as its scope will permit, either the trend or lack of trend, as the case may be, toward the use of a particular type of cutting agent for a given maching operation on a given kind of metal. It is based on information obtained from sixty-eight of the large users of cutting fluids in this country. Nine tables are presented. The first of these is a general summary. It lists the number of plants using any of three general types of cutting agent (dry, water or emulsions, oils or oil mixtures) for each of nineteen maching operations on eight kinds of metals. Each of the remaining eight tables gives more detailed information pertaining to the cutting agents used for the various operations on a given metal.

THIS report contains the tabulated returns from the blank chart published as Appendix No. 2 of the previous report,[4] which was distributed to the largest users of cutting fluids in the United States and returned by them with the blanks filled in.

This chart with its accompanying notes is practically self-explanatory. The upper portion provides spaces for indicating the types of cutting fluids used with nineteen of the common machining operations on eight kinds of metals, extra spaces being provided for operations or materials not listed. The lower portion was provided as an aid to the user in properly classifying the cutting fluids into general groups. Nearly all of the replies received contained the information in a suitable form.

Usable data were received from 75 plants of 68 of the large users of cutting fluids in this country. These data comprise over 12,000 individual returns, representing current practice of the leading manufacturers of automotive, steam, and electrical machinery, machine tools, and other products.

In some instances the information returned was vague or incomplete. Thus on several of the charts the trade name but not the classification of the cutting fluid was given. Accordingly a questionnaire was sent to the producers of the fluids mentioned by the users, and to some others, to obtain information (considered as confidential and not for publication) regarding the ingredients of various trade-name fluids. For the most part these companies gave the desired information, thus amplifying the scope of the data obtained from the users' charts.

Correlation of Data. An attempt has been made to correlate the data by the use of composite tables which are essentially a summary of all those received from the various companies.

The first and least complex of these is Table 1. In this the eight materials are listed across the top and the nineteen operations along the left border. Each column for a given material is subdivided into three parts for indicating the general type of cutting agent used. The headings for these sub-columns, A, B, and C, denote "dry" (including air-blast), "water or emulsions," and "oils, oil mixtures, etc.," respectively. In order to simplify the table, the lines for indicating the kind of duty for each operation have been limited to two; those labeled L indicate light or finishing cuts, and H heavy or roughing cuts.

The numbers recorded in each individual space in Table 1 indicate the number of plants that used that type of cutting agent on the particular operation, kind of duty and material indicated by the headings at the top and along the left border. For example, in the turning of low-carbon steel while making heavy or roughing cuts, 17 plants reported that they did the operation dry, 27 used water or a water emulsion, and 19 used an oil or oil mixture without water.

In some instances the manufacturer indicated that a particular cutting agent was used for all kinds of duty in a given operation. Wherever this occurred it was assumed that both types were implied, and that particular cutting agent was then counted under both H and L. In the few cases where a plant reported more than one kind of fluid for a given operation, for the sake of simplicity each fluid was given full credit for the operation. This was considered justifiable since the instances were few and at best the table is a very rough approximation.

A more detailed correlation of the data is given by Tables 2 to 9, inclusive. Each of these summarizes the returns for a given kind of metal. The 19 operations with two kinds of duty and the three general types of cutting agents are listed as in Table 1. Sections B (water or emulsions) and C (oils, oil mixtures, etc.), however, are each subdivided into four columns.

In the first column, labeled "Number of Users," is given the total number of plants which reported the use of that general type of fluid for the given operation. The second, labeled "Kinds of Fluids of Known Formula," indicates the number of kinds of fluids of that type that were mentioned, for which definite information regarding their formulas was available. The number of plants that reported a fluid that was known to be of the given general classification, but upon which definite information regarding its formula was incomplete, is listed in the third column labeled "Plants Reporting Fluids of Unknown Formula." In the fourth column, "Fluids Most Used," there are listed by symbols the fluids of known formulas that were most frequently reported for a given operation. The small subscript number after each symbol represents the number of users who reported the use of that particular fluid for the given operation.

As an example of the information obtainable from Tables 2 to 9 inclusive, consider the case of rough or heavy turning of low-carbon steel as given in Table 2. Seventeen plants reported that they did this operation dry; 27 reported the use of water or water emulsions. Among the various fluids of this type reported, there

KEY TO SYMBOLS

Symbols for Kind of Duty
- H = Heavy or roughing cut
- L = Light or finishing cut

Symbols for Class of Fluid Used
- A = Dry cutting, including air-blast
- B = Water or emulsions
- C = Oils, oil mixtures, etc.

Symbols for Individual Fluids

In Class B
- E = Water + alkali
- F = Water + alkali + fatty oil
- G = Water + alkali + fatty oil + mineral oil
- J = Water + fatty oil + mineral oil
- K = Water + fatty oil + mineral oil + soap
- M = Water + mineral oil + soap
- Z = Water + oil + sulphur

In Class C
- N = Fatty oil
- P = Fatty oil + mineral oil
- Q = Fatty oil + mineral oil + kerosene
- R = Fatty oil + mineral oil + kerosene + sulphur
- S = Fatty oil + mineral oil + sulphur
- T = Fatty oil + turpentine
- U = Mineral oil
- V = Mineral oil + kerosene
- W = Kerosene
- Y = Beeswax

were 5 different kinds of which the ingredients were known; 7 reported fluids upon which information was incomplete; and "water + mineral oil + soap" (M) was the fluid most frequently reported, this type of fluid being used by 13 plants. Nineteen reported the use of oils or oil mixtures. Among this type of fluids 6 kinds were of known formula, and 3 plants reported fluids upon which information was incomplete. Two types of oils were reported most frequently, blends of fatty and mineral oils (P), and blends of fatty and mineral oils + a small percentage of sulphur (S), the former being reported by 7 and the latter by 5 plants.

Kind of Cutting Agents Reported. The following basic materials were used to make up the numerous cutting agents reported: water, alkali (usually some form of soda), animal fats and oils, vegetable oils, mineral oils (including kerosene), carbon tetrachloride, turpentine, sulphur, soap, whitelead, beeswax, talc, lampblack, petrolatum, and compressed air in the form of air-blast.

Discussion

W. YOUKMAN.[5] In the general summary there is little agreement among the users as to the proper cutting fluids for turning, boring, and slotting operations on steels, while in the case of non-ferrous metals and cast iron there appears to be a fairly definite agreement. In practically all of the other operations on both ferrous and non-ferrous metals, there seems to be a definite trend toward some sort of an agreement as to the type of cutting fluids to be used. On the other hand, the differences in practice which do exist suggest the need of further study to furnish definite data on which to base an improved practice in the future.

O. W. BOSTON.[6] The report, based on a questionnaire submitted to a number of users of oils, shows in a very general way some interesting trends so far as the use of the three classes of cutting fluids is concerned. Specific information, however, seems to be lacking, and the value of the paper for commercial or scientific purposes is questioned.

It seems unfortunate that the much-used medium carbon steel was not included among the materials reported on. There appears to be some confusion in Table 9 as to whether "aluminum" is the pure aluminum or aluminum alloy. Pure aluminum machines differently from its alloys, so that this table gives

[5] Manufacturing Department, Western Electric Company, Chicago, Ill.

[6] Professor of Shop Practice, Director of Engineering Shops, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

results that are ambiguous and probably questionable. The brass reported in Table 7 probably covers a wide variety of compositions. Some distinction should have been made between those of the leaded and non-leaded types because of their difference in cutting action.

In Table 6 and elsewhere the report of the fluids most used does not include class A, which appears to be used most commonly. Also class A, referred to as dry cutting, including an air blast, probably is meant to include air suction, which is used most commonly in production work to remove the fine particles of dust of the cast iron, as well as to furnish, perhaps, a slight degree of cooling. The use of an air blast in cutting cast iron is not common, although the tabulations do not point this out.

Many users of cutting oils buy simply by trade name, and it seems only appropriate that such a classification should specifically state the exact type, specific composition, or trade name, which according to the fundamental classification is definitely located in the group. The exact composition of each trade-name composition would, of course, have to be known. A classification that is used by the writer is appended as a suggestion. This table gives a variety of sub-classes under each main heading, and under each sub-class are given several specific types. Oils are divided into six main headings under *D*, as fixed oils, mineral oils, compounded or blended oils, sulphurized mineral-oil bases, sulphurized lard-oil bases, and mineral oil with oleic acid. The fixed oils are subdivided into animal, fish, and vegetable oils, each of which is further subdivided into specific oils. Mineral oils are subdivided into kerosene and lubricating oils of various viscosities, such as 28 deg. B. pale paraffin, red engine oil, etc. It probably would be more satisfactory to represent the paraffin, red engine, and heavy engine oils by their viscosity at 100 deg. fahr., as indicated. Under the oil classification, therefore, lard oil would be represented by *D* 1 *a* (1) pale mineral oil (100 viscosity at 100 deg. fahr.) by *D* 2 *b*, etc. Under such a heading either viscosities or percentages could easily be added, so that the information given would be specific. For instance, if in grinding, tri-sodium phosphate were used, mixed in proportion of 1 lb. of grinding compound to 50 lb. of water, it could be specified as *C* 3 *e* (1 to 50). This 1 to 50 may be expressed as 2 per cent.

It is realized that this classification should be extended to cover all desirable types of oils or trade names, but in the end the classification would be specific, or if only general information was needed, only the first one or two symbols of the classification could be used.

As a member of the sub-committee sponsoring this report, the writer is offering his suggestions because he is not wholly in accord with the report. He feels that such a classification should be of value to the man in the shop, the production engineer, or the purchasing agent, and he very much questions the value of the information presented for this purpose.

Classification of Cutting Fluids

A Dry
- 1 Dry
- 2 Air blast
- 3 Air suction

B Aqueous solutions
- 1 Water
- 2 Water plus alkali
  - *a* Borax
  - *b* Soda ash or sal soda
  - *c* Trisodium phosphate
  - *d* Also various trade names representing various compositions

C Emulsions, soluble oils and compounds
- 1 A mineral oil compounded with a neutralized sulphonated fixed oil; to be mixed with water
- 2 A mineral oil compounded with an alcoholic solution of soap; to be mixed with 10 to 50 parts of water
  (Various compositions designated by trade name or symbol)
- 3 A cutting paste made of thick soap solution and mineral oil; to be mixed with 10 to 50 parts of water
  (Various compositions designated by trade name or symbol)
- 4 Non-alcoholic soap-base soluble oils
  (Various compositions designated by trade name or symbol)
- 5 Ohter special mineral-lard oils; emulsified with an alkali
  (Various compositions designated by trade name or symbol)
- 6 Synthetic mineral soluble oil
  (Various compositions designated by trade name or symbol)
- 7 Milk
  - *a* Fresh milk for cutting copper
  - *b* Sour milk for cutting aluminum

D Oils
- 1 Fixed oils
  - *a* Animal
    - (1) Lard
    - (2) Tallow
    - (3) Neat's-foot
    - (4) Wool
    - (5) Horse
    - (6) Sperm
    - (7) Whale
  - *b* Fish
    - (1) Menhaden
  - *c* Vegetable
    - (1) Olive
    - (2) Rapeseed
    - (3) Cotton seed
    - (4) Mustard seed
    - (5) Castor oil
    - (6) Peanut oil
    - (7) Soya bean oil
    - (8) Corn oil and distillate oils
    - (9) Creosote
    - (10) Turpentine
    - (11) Rosin
- 2 Minerals oils
  - *a* kerosene
  - *b* (100 viscosity at 100 deg. fahr.)
  - *c* (200 viscosity at 100 deg. fahr.)
  - *d* (300 viscosity at 100 deg. fahr.)
- 3 Compounded or blended oils
  - *a* Fixed
  - *b* Mineral
  - *c* Fixed and mineral
    (Various compositions designated by symbol or trade name)
- 4 Sulphurized mineral oils (straight or diluted with 3 to 6 parts *D* 2 *b*)
  (Various compositions designated by symbol or trade name)
- 5 Sulphurized lard-oil base (straight or diluted with 5 to 20 parts *D* 2 *b*)

(Various compositions designated by symbol or trade name)

6 Mineral oil with oleic acid

(Various compositions designated by symbol or trade name)

RALPH E. FLANDERS.[7] The writer disagrees with the suggestion that cutting fluids should be called coolants on the assumption that their only function is to carry away heat.

Most "coolants" perform two functions; that of carrying away heat and also that of lubricating or otherwise affecting the cutting action so as to give a smooth finish. In general, the use of oils tends to improve the finish, but decreases the heat-carrying power. While pure water, with the addition of some chemical to prevent it from rusting the machine, is superior in heat-carrying power, it does not give a good finish. Most practical cutting compounds are a compromise between these two qualities.

The writer was much impressed with the necessity for lubricating characteristic in cutting oils in connection with a recent experience. Some Acme thread chasers had been made which were to be used in a shop in St. Louis. In our own shop on the material used in the St. Louis shop these chasers cut a beautiful thread. In the customer's shop in St. Louis they cut very poor threads. Nothing that could be done at long range solved the mystery of good performance in our shop and of poor performance in the customer's shop. A visit with two or three days' investigation brought no light to the problem until the cutting oil came under suspicion. It was shut off from the machine, and a can of ordinary emulsion of some sort from a nearby engine lathe was turned on the bar of stock while the thread was being cut, and instantly a fine finish was obtained. In other words, the supposedly cheaper cutting compound gave very much better results than the oil.

It is surmised that the oil used was lacking in that quality of "oiliness" of which Dr. Hershey speaks, while the very small amount of oil in the cutting compound was rich in that quality. It is hoped that some time apparatus will be devised to measure this quality more or less directly as it seems to be a very important one.

While it is indubitable that oils and cutting compounds have some lubricating effect which affects the quality of the finish, this action must take place on the under side of the chip between the tool point and the work. At cutting speeds of 75 to 150 ft. per min., it is very difficult to understand how enough of the liquid gets in there to make any particular difference, but get in there it does somehow, perhaps by capillary attraction or perhaps by adsorption—whatever that may be. The whole matter is mysterious, but that does not prevent making practical use of the mysterious qualities.

[7] Manager, Jones & Lamson Machine Company, Springfield, Vt. Mem. A.S.M.E.

AUTHOR'S CLOSURE

Professor Boston's point regarding symbol (A), dry cutting including air blast, is well taken, since with few exceptions the symbol (A) refers to the usual type of dry cutting. Air blast was reported by one plant only. It was used for drilling and reaming operations on cast iron and for threading and tapping operations on cast iron and brass. Air suction was not mentioned by the plants that answered the questionnaire.

The main part of Professor Boston's discussion is built around the question of specific versus general information. It is realized that a minutely detailed classification of operations, metals, and cutting fluids would be more desirable. It should be pointed out, however, that a questionnaire of a scope suitable to obtain this complete detailed information would of necessity have to be too elaborate from the standpoint of obtaining reasonable cooperation from the plants. Thus the choice boils down to either sending out a questionnaire of a general nature from which a reasonable percentage of replies will be received or one that is so detailed as to require an expenditure of more work to fill in than can reasonably be expected.

In conclusion it should be noted that the classification to be followed in analyzing the returns was not optional with the present author, as it was fixed by the questionnaire sent out, which in turn formed a part of the previous Progress Report[8] and had already been approved by the sub-Committee.

MSP-52-9

Economies Which May Be Effected in Power Transmission

By W. W. NICHOLS,[1] DETROIT, MICH.

From an economical standpoint of maintenance, power-transmission equipment is not given careful consideration by management. It should not be left to the supervision of some old-time millwright. Belting is not given a close enough inspection upon its receipt to determine if it meets all the requirements laid down by the specifications for its purchase. Many machines upon production work are over-belted, and little attention is given to the correct determination of the size of belt necessary for the work. Heavier belts could be installed profitably. By this means unnecessary wear and tear upon countershaft clutches would be eliminated. More attention should be given to the application of the correct size of motor to individually motor-driven machine tools. Great loss and low power factor result from the methods now pursued. The question of group driving and the economies effected thereby are deserving of being more closely considered and of having their cost compared with individually motor-driven tools, both from an initial standpoint and a maintenance standpoint.

THE installation and maintenance of power-transmission equipment are not given the careful consideration by management from an economical standpoint that is given to some of the other departments of a manufacturing plant. In order that this department may be placed upon an economical and progressive basis, management must take more interest in this subject and not leave it under the supervision of some old-time millwright who uses only rule-of-thumb methods.

Construction of Leather Belting

All leather belting should fall within $^1/_{64}$ in. plus or minus in thickness, joints and laps be constructed with non-crystallizing cement, all joints to be made against a straight edge at least 4 ft. in length, no strips to exceed 50 in. in length, faces of belt to be leveled to provide at least 90 per cent of contact upon pulley face.

All belting should be inspected upon receipt to see that the foregoing requirements are fulfilled. Many plants make the statement, "We buy our belting to specification," but when asked what method of inspection is used upon receipt, reluctantly admit either that there is no standard of inspection or that they do not know. The result is that a poor quality of material is being received, with its consequent high maintenance cost.

Determination of Correct Sizes of Belting

When machines are used upon jobbing work, they must be belted to accommodate the heaviest class of work to be handled upon the machines. However, when machines are set up to run for long periods upon the same piece, considerable economy can be effected by determining the actual amount of power required and by belting accordingly. This may be done by equipment similar to that shown in Fig. 1, consisting of an electric motor mounted upon a high-lift truck and used in conjunction with a recording watt-hour meter. In smaller plants it would not be necessary to incur the expense of a high-lift truck. The motor might be mounted upon a lift-truck platform, and sufficient weight added by means of scrap material or disused castings could be piled at the opposite end of the platform from the motor to assist in holding it steadily to the floor, various motor pulleys being used to give the correct countershaft or machine speeds.

The chart from the recording watt-hour meter will show the friction load of the machine, the maximum and minimum power required by the various tools, and the time taken for the complete cycle of operations.

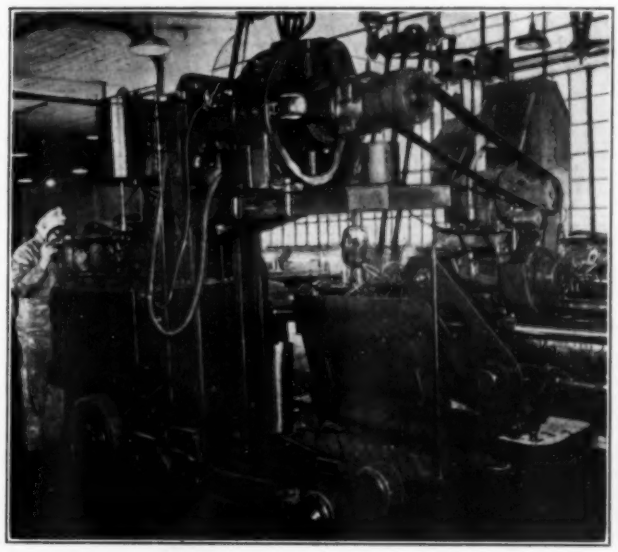

Fig. 1 Testing Equipment

The radial lines upon the recording wattmeter diagrams shown in Figs. 2 to 5 indicate half-minute intervals so that the time for a complete cycle of operations may be readily ascertained. The longitudinal lines represent the power input to the motor in watts. By this method, the total time and total power input to the motor can be measured readily and the necessary width of belt required upon the machine can be determined. By means of a wattmeter diagram, the power required for driving tools can be determined as changes in the cutting angles are effected. As an illustration of this, in one plant tests were made upon twist drills as originally ground, and it was found that 28 holes per grind was the maximum which could be produced. After experimenting with thinning the points of these drills, 220 holes were produced and an average of 178 is now being maintained. These drills were in operation upon alloy steel. The field for the application of these methods is so large and varies so greatly in the individual plants, that it is hardly possible to do more than merely to outline their application in a paper such as this, but it is the author's belief that if serious consideration is given to this subject by plant engineers or superintendents, that they can readily adapt these methods to their own conditions.

[1] Vice-President and Mechanical Engineer, D. P. Brown & Co. Mem. A.S.M.E.

Contributed by the Machine Shop Practice Division and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Fig. 2 was taken from a gear-hobbing machine driven by a 5-in. belt. Upon calculation of this chart it was found that a 2-in. belt would perform the work, and such a one was installed, much against the will of the operators, but it is doing the work required. Another instance is that of a battery of over 300 Gleason gear shapers where a 2-in.-fabric belt has been installed in place of a

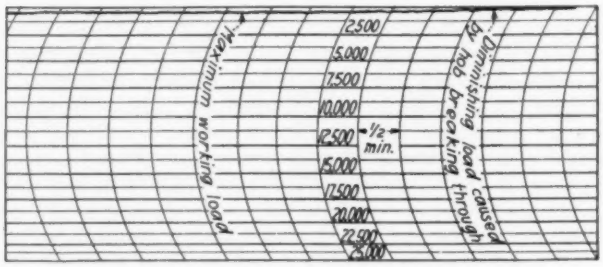

Fig. 2 Wattmeter Diagram From Gear Hobber

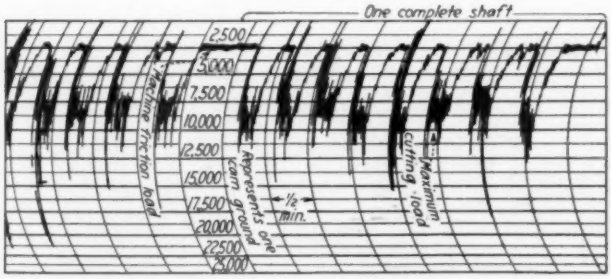

Fig. 3 Wattmeter Diagram From Norton Grinder

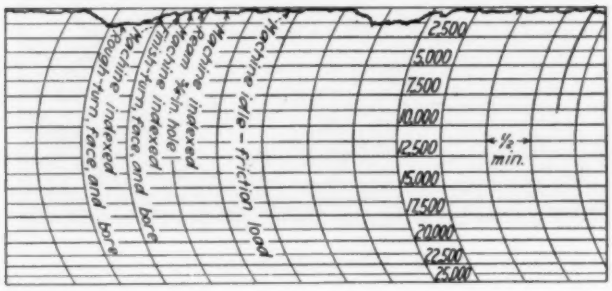

Fig. 4 Wattmeter Diagram From Potter & Johnston

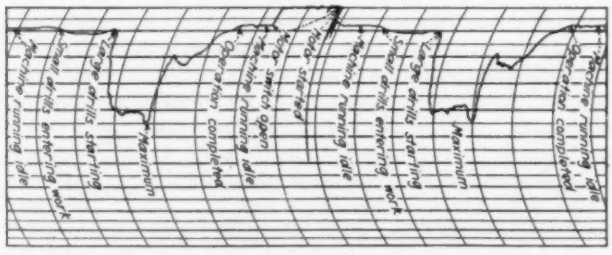

Fig. 5 Wattmeter Diagram From Rockford Drill

3½-in. double leather which effects a saving of about $35 a machine, or a total of around $10,500.

Fig. 3 was taken from a Norton grinder upon camshaft work. Note the high peak caused by the operator taking too heavy a cut.

Fig. 4 was taken from a Potter & Johnston turret lathe and shows the amount of power required for each operation.

The economies effected by these charts would not have been made if the old rule-of-thumb methods had been in use.

Heavier Weight of Belting

All have seen belts put upon pulleys at such a high tension that a rope was necessary to get them on. This means additional friction load to be overcome, wear and tear upon clutch or loose pulley and bearing wear, and additional cost of maintenance. These conditions can be remedied by the use of a heavier weight of belting, provided the pulleys are of sufficient diameter, or by wider belts of a lighter weight. Taylor's and Barth's recommendation of 190 lb. per sq. in. of belt section as the correct tension for belt application has been found by the author to be the most economical. To temporarily get out of the difficulty of a belt not pulling the required load, a rider belt has been added to the original one.

Motorization of Machine Tools

There is room for considerable improvement in the methods now employed in determining the correct size of motor upon individual machines. This will be of valuable assistance to both the machine-tool manufacturer and the user. There are two sides to this question—the manufacturer's and the user's. Often the manufacturer does not receive a definite description of the work to be performed upon the machines from the user, and the manufacturer recommends the size of motor sufficient for the maximum cut the machine is capable of pulling, which results in all probability in a very low power factor.

If the user would inform the manufacturer regarding the class of material to be operated upon and at what feeds and speeds, the latter would be able to determine the most satisfactory size of motor. But a still better method would be for the user to send sufficient of his material to the machine-tool maker for him to experiment upon and determine what would be the maximum production of the machine. There is room for a more thorough investigation by users of machine tools to determine the maximum production which machines can develop. Instances of this were brought out in one plant, where the testing outfit shown in Fig. 1 was used, indicating that production in some instances could be doubled without injury or increased grinding of tools. Other instances have occurred where requisitions for additional tools were proved to be unnecessary after tests were made. Some interesting facts developed regarding the determination of motor sizes for machine tools while the author of this paper was assisting A. F. Denham of *Automotive Industries* in the compilation of data.

The electric motor survey conducted by the National Machine Tool Builders' Association, covering all industries, showed motor sizes were specified as follows:

	By the tool manufacturer	By the user	By the dealer	Not specified
Fractional hp., %...	89	8	2	1
1–10 hp., %.....	37	47	15	1
10–15 hp., %.....	30	57	13	.

Mr. Denham[2] says, "This would seem to indicate that, taking all industries together, as the size of motors increases, more and more of the specifications come from the purchaser. Peculiarly enough this does not seem to apply to the automotive industry, to judge by replies from a number of leading machine-tool manufacturers. Thirteen out of fourteen of the largest manufacturers from whom replies were received state that they customarily specify all motors for machine tools for the automotive industry, the tools representing all types and including much special machinery.

"The manufacturers from whom replies were received can be

[2] From *Automotive Industries*, Aug. 11 and 18, 1928.

separated into four groups. In the first and largest group are those who clearly state that it is their custom to specify a motor size which will take care of the maximum load capacity of the tool without reference to the type of work for which the tool is to be used.

"In the second group can be placed those manufacturers of machine tools who offer more than one motor size for a specific tool. It will be noted, however, that even these make no effort to determine actual power requirements.

"In the third group are classed those manufacturers who determine motor sizes by computations of power required for the specific operations for which the machine is intended, basing this, by means of an empirical formula, on the amount of metal removed.

"Two manufacturers only among those replying are in the fourth group, those who actually determine the horsepower requirements by test."

From these quotations the chaotic condition this motorization of machine tools is in can be seen. In further substantiation of these remarks, a chart was taken from a Moline Hole Hog used in finish-reaming cylinder blocks. The machine was equipped with a 15-hp. motor, whereas less than 5 hp. was required for the operation. In one plant with which the author is familiar, 235 tests were made upon motor-driven tools and group drives having a total of 2100 motor hp. connected. After these tests were made, reductions to the amount of 1100 hp. were made in connected motor horsepower, some of the lineshafts of the groups showing a friction load of 56 per cent.

Fig. 5 shows a case of under-motorization of a Rockford drill. a 5-hp. motor having been originally installed, but upon changing the machine over to another operation, this was determined to be too small and a 7.5 hp. motor was found to be required.

Group Drive

The question of individual drive for machine tools or of group drive for them provides many arguments for and against each system. There is no question that smaller total motor horsepower is required for group drive than for individual-motor drive. Take as an example a battery of ten polishing stands which can be driven by a 20-hp. motor as a group, but if individually driven a 5-hp. motor is required for each stand to take care of the peak load which occur at times.

Shop-layout and working conditions must be considered in addition to the question of how often machines have to be rearranged, together with the comparative cost of shafting installation in comparison with electric wiring before determining which class of installation is to be used.

Flywheels

In recent years the application of flywheels upon intermittent drives, such as board drop hammers and polishing stands, seems to have been forgotten, also the flywheel effect of the old cast-iron pulleys in comparison with wood and pressed steel.

The author assisted in designing the shafting equipment for a large forge shop about four years ago and used a 5000-lb. split flywheel as a receiving pulley from the motors. This has eliminated belt troubles, and in fact the majority of the original belts are still in operation on both the motors and the hammers.

From the foregoing remarks it is hoped that the author has cited sufficient examples to show the necessity for management taking more interest in this question of power transmission and the appointment of a capable engineer to supervise it. He has not touched upon the economies which can be effected in the boiler room, power house, or wiring systems, all of which contain as great or possibly greater opportunities for economy than does the manufacturing division of a plant.

Discussion

Claude O. Streeter.[3] The paper brings out many valuable points which, if given consideration, will unquestionably result in economies. However, there are some points brought up which should be considered a little more carefully in regard to their practicability.

Construction of Leather Belting

In discussing this point the writer has in mind a commercial and not a special product. Consequently, the variation of plus or minus $^1/_{64}$ in. is not practical due to the fact that the natural variation in thickness of a piece of leather is $^4/_{64}$ in. In other words a belting strip which is $^8/_{64}$ in. thick on the shoulder end will be $^{12}/_{64}$ in. thick on the butt end, and approximately $^{10}/_{64}$ in. thick mid-way between these two points.

In the construction of leather belts it is necessary that joints be broken, which will result in the shoulder end which is $^8/_{64}$ in. thick being placed at this mid-way point which is $^{10}/_{64}$ in. thick, thus making the thickness at this point $^{18}/_{64}$ in. This will also bring the $^{12}/_{64}$ in. butt end opposite the $^{10}/_{64}$ in. middle point in the other ply thus making a $^{22}/_{64}$ in. total thickness, thereby making $^4/_{64}$ in. natural variation mentioned above.

This construction discussion pertains to double belting.

Of course this thickness variation can be reduced by the expedient of splitting the heavy sections or shimming the light sections, but when it is considered that the splitting would be done on the flesh side, and further consider that this flesh side contains approximately 50 per cent of the tensile strength of the whole piece, the fallacy of splitting off this strength, which would result in excessive stretch, is apparent.

Then again, when the size of the shim is considered which would be necessary to build up the light section and further consider the undesirability of shims in double belts, one is again impressed with the fact that this is impractical.

The maximum length of 50 in. specified is also economically unwise due to the fact that a belt bend which is 48 in. long on the backbone will be 54 to 56 in. long six to eight inches from this backbone due to the natural contour of the butt end of the hide. This extra length of material is very excellent stock, consequently the fallacy of cutting it off with the resultant waste is apparent.

It would seem to be much better if the maximum length were specified as 54 in. and the minimum length as 36 in. including laps, for single belts. For double belts the minimum should be 20 in. long for one-eighth the total pieces used, no two of these short strips to come consecutively. This short length in double belting is absolutely necessary due to the necessity for breaking joints as previously mentioned, and the natural variation which will occur in the length of belting strips.

In regard to leveling, to provide at least 90 per cent of contact it is assumed that this means leveling of the finished belt, and such being the case this leveling would occur on the grain or smooth surface. When it is considered that this grain surface has a high tractive value one is impressed with the fact that anything which removes this surface will detract from that value, and consequently is undesirable.

The contact of the belt surface on the pulley faces when the belt is new is not complete due to the fact that the belt has not broken in on the drive, and the various fibers have not become equally compressed. The result is that the surface of a new belt has a mottled appearance, but after the belt has run for a few days this mottled appearance disappears, and the belt takes on a uniform surface finish.

All know that when new, a leather belt is at its poorest as a

[3] Mechanical Engineer, Engineering Dept., Graton and Knight, Worcester, Mass.

power transmitter and also that it improves with age; consequently strong consideration should be given against the removal of the grain surface of belting for commercial purposes. Special belting is another consideration entirely, but as this evidently is not a point to be considered in connection with this paper at this time no discussion of it seems necessary or advsiable.

Inspection

The point raised here is a very excellent one, and if people who think they are buying to a specification would merely read this one paragraph they would immediately appreciate how valuable their specification is to them. As a matter of fact of the thousands of leather-belting specifications which are used for obtaining bids throughout the country, there are very few by which the goods received are checked up for the simple reason that the people using them have no facilities for this checking.

This practice works an extreme hardship on the leather-belting manufacturer who bids to a specification with the intention of supplying goods which will meet the specification due to the fact that the small unscrupulous concern, knowing that the specification is not enforced, puts in a price which he knows will be acceptable to the concern buying, and plans to furnish the belting in accordance with that price.

The comments in regard to determination of correct sizes of belting are particularly apropos, and the mechanism described for this work is not basically new as it has been used by many investigators. The one feature about it which is new is the use of the high-lift truck for the installation of the motor. The usual method is to have a portable motor which can be fastened to the floor very rigidly.

One thing about the high-lift truck equipment is that it would be particularly difficult to establish and maintain proper alignment, and it would seem that a considerable amount of difficulty would be experienced from vibration, particularly when the platform was at a comparatively high level.

The statement in regard to the installation of fabric belting of reduced width on gear shapers replacing double belts is particularly interesting, but the fact must not be lost sight of that first cost is not the whole story when leather belting is replaced with fabric belting. The low transmitting efficiency of the fabric belt may readily eat up, in power and production loss, more than could be saved in the purchase price. This statement in regard to the fabric belting cannot be termed "sour grapes" on the writer's part as his company manufactures and sells both fabric and leather belting.

The comments in regard to high tensions are particularly well taken, but many times belts are roped on to drives because of the ease of this method of installation of endless belts, particularly on overhead drives, and while they will be tight when first roped on, this is only a temporary condition, and is soon relieved by the stretch and elasticity in the belt.

The real meat in this statement is the fact that belts should be properly proportioned to the work to be done on any drive, and then power transmission will be economical with difficulties reduced to an absolute minimum.

The tension of 190 lb. mentioned is practical, but if anything it is a little bit on the high side when it is considered that 190 lb. per sq. in. of cross section will equal approximately 50 lb. per in. of width per strand for a total initial tension of 100 lb. for a single belt. The use of a rider belt is a common one and seems to be open to no comment.

The comments on the motorization of machine tools are most certainly extremely well taken. The one possible difficulty to be considered is the fact that machine tools have a habit of changing hands. Consequently, if the tool is not motored to maximum capacity in the plant it was originally purchased for, because the work does not call for it, the next purchaser of this tool may be in considerable difficulty because his machine is under-motored due to the heavier type of work he is doing. This, of course, can be overcome by each purchaser of this tool endeavoring to get the manufacturers to ascertain as to what power is required for his particular work. This will be easy enough where the used tool is purchased from its original manufacturer, but probably would be deemed a hardship by that same manufacturer if it was purchased from some other source. This may not be a particularly vital consideration, but one which it would do no harm to consider.

The comments on group drives and fly wheels are very interesting and contain considerable food for thought, and if more thought was given, particularly to the group drive consideration, there would be less individual motor equipment used than is the case at the present time. In other words, industry seems to have gone individual-motor crazy, and while there is a possibility of being equally ridiculous on the group-drive basis this is rather remote, but should not be lost sight of.

MSP-52-10

Test Code for High-Speed Steel for Turning Tools

Report of Sub-Committee "D" on Properties of Materials[1] of the A.S.M.E. Special Research Committee on Cutting of Metals

PREPARATION of a test code for tool steels brings into consideration the composition and the heat treatment of the tool steel to be tested as well as the characteristics of the material to be cut by the test tools and the general conditions governing the test.

The American Society for Testing Materials in 1916 initiated the preparation of tool-steel specifications by Committee A-1 on Steel appointing Sub-Committee XIV on Tool Steel. The early meetings of this sub-committee showed that there were no generally accepted methods of chemical analysis for tool steels. Therefore, Committee XII on Methods of Chemical Analysis, of Committee A-1, was requested to develop standard methods of analysis applicable to tool steels. The following have been prepared:

Serial designation A 33-24	Standard Methods of Chemical Analysis of Plain Carbon Steel
Serial designation A 55-24	Standard Methods of Chemical Analysis of Alloy Steels.

The committee discussions showed that there was a very large number of tool-steel compositions employed. One member stated that his company employed over 2000; that there was a very wide range of applications for tool steels for cutting, for example, lathe and planer tools, milling-machine tools, drills, taps and dies, etc., tools for woodworking and other industries, and that the use of a specific tool-steel composition was not uniform throughout the United States. It was manifestly impossible to write a specification which would state a specific composition. Therefore, it was decided to write each specification to permit the specific composition being made a matter of agreement between the purchaser and vendor. A table was incorporated in the specification establishing permissible variations from the agreed upon composition. For example, the following table is applicable to carbon tool steels:

		Permissible variation, per cent Over	Under
Carbon		0.05	0.05
Manganese	when under 1.00	0.10	0.10
	when over 1.00	0.20	0.20
Phosphorus		0.005	..
Sulphur		0.005	..
Silicon		0.15	0.15

Other elements as agreed.

To facilitate inspection a table of permissible dimensional tolerances was incorporated in the specification. Methods for marking the tool steel, for preparing it for shipment, and for obtaining the sample for chemical analysis are described in the specifications. In case of dispute as to chemical composition the standard methods of chemical analysis previously referred to are to be used. The following specifications have been prepared:

Serial designation A 71-26	Standard Specifications for Carbon Tool Steel
Serial designation A 92-26	Standard Specifications for High-Speed Tool Steel
Serial designation A 115-28	Standard Specifications for Alloy Tool Steel.

These specifications apply to tool steels in general use. The sub-committee is prepared to assist in any research work which may be of service in developing test codes for tool steels.

The American Society for Steel Treating has been developing practices for heat treatment of steels, including tool steels. In view of the importance of proper heat treatment for tool steels the recommended practices developed by that Society have been appended to the carbon tool-steel and to the high-speed tool-steel specifications, but on account of the wide range of permissible compositions covered by the alloy tool-steel specifications reference only is made to the recommended heat-treatment practices developed from time to time.

The American Society of Mechanical Engineers in 1923 appointed a special research committee for cutting of metals to consider, among other subjects, the cutting performance of tool steels. The work of this committee is closely related to that of the corresponding committees in the two societies mentioned.

A review of the applications of tool steels resulted in the selection of high-speed tool steel as the subject for the first test code. Other test codes can be developed as soon as the essential characteristics of the high-speed tool-steel test code have been definitely determined. The type of test code will depend upon whether or not the tests are to be conducted in accordance with laboratory procedure or in accordance with the usual facilities available in a machine shop. A tentative test code has therefore been prepared to permit the omission of some of the test apparatus, and the test computations indicated in Fig. 1 can be reduced to those required by the experimenter.

The tentative test code is presented at this time with a view to obtaining constructive criticisms, to the end that a satisfactory test code may be developed later.

A.S.M.E. Tentative Test Code for High-Speed Tool Steel

Code. This test code is applicable to high-speed tool steel intended for manufacture of lathe and planer tools.

Steel Specifications. The material shall be in general accordance with the Standard Specifications for High-Speed Tool Steel, A92-26, prepared by The American Society for Testing Materials.

Sample. The sample bar for test tools shall be $\frac{1}{2}$ in. $\times$ 1 in. $\times$ 72 in. long. The bar shall be cut into five approximately equal lengths for test tools and identification number stamped on each length.

---

[1] The personnel of this Sub-Committee consists of: L. H. Kenney, *Chairman*, Mech. Engr. U. S. Navy Yard, Philadelphia, Pa.; H. J. French, Metallurgist, International Nickel Co., Bayonne, N. J.; J. O. Keller, Professor, Pennsylvania State College, State College, Pa., and W. W. Nichols (ex-officio), Detroit, Mich., *Chairman*, A.S.M.E. Special Research Committee on Cutting of Metals.

Contributed by the A.S.M.E. Special Research Committee on the Cutting of Metals and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

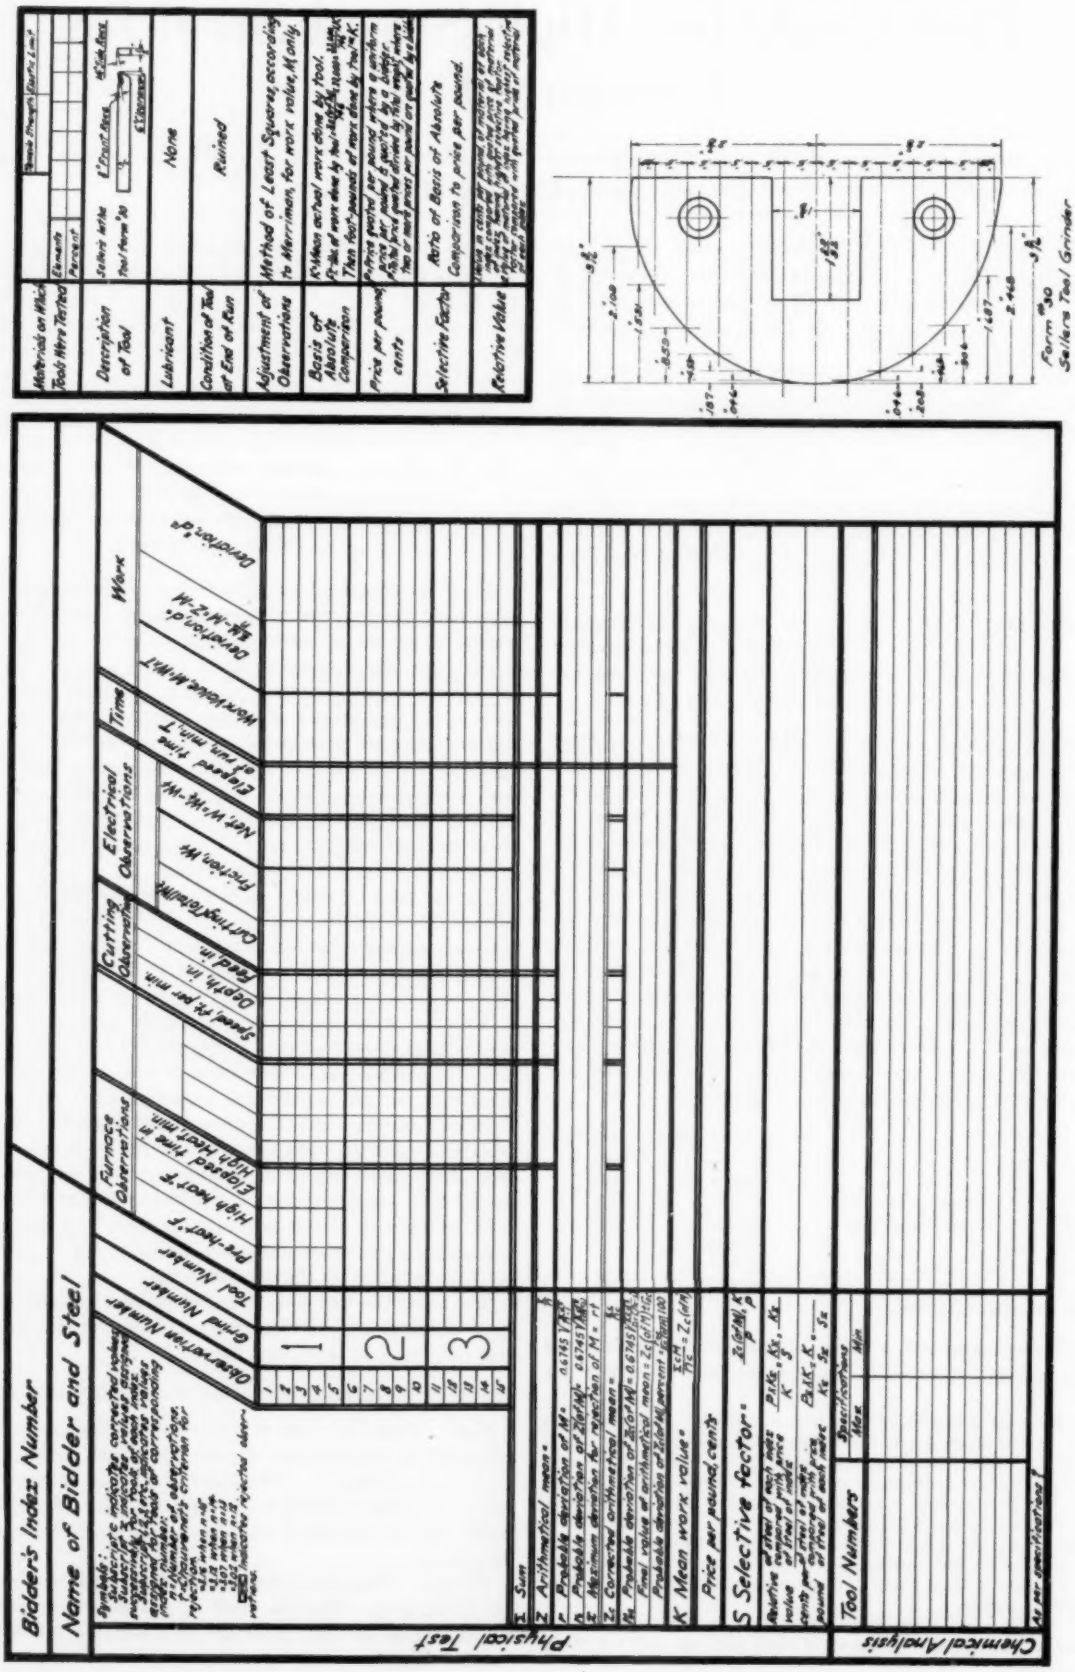

FIG. 1 LOG FORM FOR DATA

Grinding. The test tools shall be ground without forging and previous to heat treatment to approximately the specified tool form, Fig. 1. After heat treatment and after each failure on the test cut, the tools shall be ground to the specified tool form, care being taken to remove the material affected by the previous cut. It is essential that this work be done carefully and accurately.

Heat Treatment. The heat treatment for the test tools shall be in general accordance with the Recommended Practice for Heat Treatment prepared by The American Society for Steel Treating and appended to the A.S.T.M. Standard Specifications referred to.

Test Forging. The nickel-steel forging on which the sample tools are to be tested should be originally approximately 2 ft. in diameter by 10 ft. long. The chemical composition shall be approximately as follows:

Carbon, per cent	0.30–0.40
Manganese, per cent	0.50–0.80
Phosphorus, per cent	not over 0.040
Sulphur, per cent	not over 0.045
Nickel, per cent	3.25–3.75

The physical characteristics shall be approximately as follows:

Tensile strength, pounds	95,000
Proportional limit, pounds	65,000
Elongation in 2 in., longitudinal per cent	21
Reduction in area, longitudinal per cent	45
Brinell hardness	190
Rockwell hardness	C19

Test Cut. The test tools are to be subjected to a cutting test in a lathe on the test forging, the depth of the cut being $^3/_{16}$ in., the feed 0.044 in. per rev., and the cutting speed about 56 ft. per min. The test speed selected, however, should give for a representative type of tool steel a cutting life of from 15 to 20 minutes. The cutting speed so selected shall be standard for the test.

Work Done by Cutting Tool. A graphic wattmeter may be installed to determine the motor input when the lathe is operating with and without cut, or any equivalent means of measuring the power may be used. The difference in power required when the lathe is operating with and without cut is a measure of the work done by the test tool in cutting the test forging.

Tabulation of Data. The observed data may be recorded on the log form, Fig. 1 on page 116, and the indicated computations made.

Selective Factor. The selective factor, Appendix No. 1, is the ratio of the work done to the cost per pound of the material under test. The factor serves as a basis for comparison when several samples are tested.

Discussion

O. W. Boston.[2] The writer has been an interested observer of the development of this tentative test code for the past several years. He believes that the testing of high-speed steels is done in a large number of plants, but under many different conditions and by different methods. While there may be some objections to certain phases of this test code, it will start people thinking along the line of uniformity and standardization and may eventually lead to a test code which will be satisfactory to the majority of users of high-speed-steel tools. This test code may have to be made more general, as was the case as reported by the author regarding "standard methods of chemical analyses," "standard specifications for high-speed-steel tools," and the "recommended practice for heat-treating high-speed-steel tools." Only a few years ago it was thought impossible to formulate such standards.

There may be some questions raised as to the exact nature of the work which the high-speed-steel turning tool is to do; whether it is to be used for finishing or light cuts, medium duty, heavy duty, or even so-called super-heavy duty. This might be made a part of the specifications, or several sizes of standardized cuts may be specified, better to meet the particular practical application. In other words, a tool which is to be used for taking cuts between $^1/_2$ and 1 in. in depth and, say, $^1/_8$ in. feed might prove inferior after receiving a favorable rating with test cuts $^3/_{16}$ in. in depth and 0.044 in. feed per revolution as specified.

The Sellers lathe tool, form No. 30, has been specified on a shank $^1/_2$ in. wide by 1 in. deep. It would seem desirable to have the details of this shape, or whatever shape is most desirable, specified more in detail, as many people wishing to conform with the test code might have to grind tools on grinders other than of the Sellers make. Perhaps a simpler tool shape could be used which could be ground quicker and more accurately on any grinder. The test log is of a material and condition that might be hard for many to obtain. The size is large for most plants to handle conveniently, or it may be even too large for any lathe available in many of the plants. The size, however, is of little importance so long as the diameter is sufficient to make the reduction in cutting speed, due to successive cuts, inappreciable.

The work done by the cutting tool, as determined by the wattmeter, is really a measure of machinability of the test log rather than any indication of the property of the tool material, as long as the cutting tool remains sharp and of the same geometric shape. This power consumption does not appear, therefore, to be of primary importance except as an indication of the time of tool failure, although the writer is of the opinion that all possible information which can be collected in such a test should be recorded.

The writer hopes that this test code will be given serious thought by the makers and users of tool steels and that the subcommittee may be advised as to desirable changes or additions, so that it may eventually be developed into a useful standard.

Closure

Mr. Kenney. The preparation of a Test Code for High-Speed-Tool Steel is complicated by the number of tool-steel compositions, heat treatments of these tool steels, geometric shapes of the cutting edges of the tools, coolants or lubricants, materials to be cut, types of machines in which the tools may be used, types of cutting requirements, and so on.

It may be possible in time to develop suitable laboratory testing machines which will determine the essential characteristics of cutting tools for their principal applications. It follows that a satisfactory method must be developed for comparing the performance of the tools in the shops with the laboratory tests. Not until this is done will it be possible to predict with a satisfactory degree of accuracy the shop performance of cutting tools based on laboratory data. It should be possible to develop laboratory testing machines and arrange for a number of independent investigations, the investigations to be so conducted that the data obtained will be readily comparable. With such a program it is believed that it will be possible in time to so revise the Tentative Test Code that it can be adopted as a "Standard Test Code for High-Speed Steel for Turning Tools."

What Happens When Metal Is Cut

By ORLAN W. BOSTON,[1] ANN ARBOR, MICH.

The paper constitutes a valuable contribution to research and a check in some instances upon the conclusions of other authors. This study is confined mainly to deformation as seen on the exterior of the metal. It is first of several steps which may include use of the X-ray and the moving picture to reveal more exactly what is taking place as the cutting tool advances into the metal.

IN reviewing the great amount of work done with metal-cutting tools and the lack of definite information available for use in connection with machine-tool design (Ref. 3), Mr. A. L. De Leeuw listed eleven questions which should be answered in a scientific manner. These questions are as follows:

(*a*) When we turn up a narrow disk by means of a square-nosed turning tool of which the width is greater than the width of the disk, is the action of removing the chip purely a matter of tension? Or, if not, what is it?

(*b*) Does the front end of the tool have any function at all?

(*c*) How far from the edge of the tool is the point where the chip strikes the tool?

(*d*) If the action is purely a matter of pull, and the chip does not strike the top of the tool at the cutting point, but some distance farther back, then is it necessary that the cutting edge of the tool be sharp?

(*e*) What is the nature of the lamination of the chip?

(*f*) How much power is required for the actual removal of the chip, for the friction between chip and tool, and how much for laminating the chip?

(*g*) What would be the best shape for such a turning tool for this particular turning operation?

(*h*) How does the amount of power vary with the various angles of the tool?

(*i*) If the turning operation is not as simple as the one assumed in question (*a*)—if, for instance, there is a side feed, such as in ordinary shaft-turning operations—how is the cutting action modified by this side feed?

(*j*) If the chip is removed by the action of the top of the tool—that is, if the front of the tool has no function—then what determines the nature of the finish of a cut?

(*k*) In what relation does the power required for the side feed stand to the power required for the actual removal of the chip?

The fact that these questions have been listed as subjects about which definite information is lacking indicates the complexity of the subject of metal cutting and chip formation. To this mystery was added the subject of cutting fluids, which complicates it still more. De Leeuw further indicated that many more questions might be asked after these were answered.

It is for the purpose of being able to add to the understanding of the subject of metal cutting that the following study is made.

Nature of the Investigation

After completing a series of experiments dealing with tool shape and chip size a number of years ago (Ref. 21), it occurred to the author that information of a still more elementary nature was needed. The equipment used in the investigation consisted of a large planer on which was mounted a specially designed dynamometer, so that the force on the tool in the direction of cut could be measured. This equipment seemed to be ideal for a set-up to photograph, under various magnifications, the side of the chip and tool during the process of cutting. A tool of the end-cutting type was used to remove a chip from the top of a ridge. This ridge was prepared to be $^1/_4$ in. thick, and its face was carefully ground and polished. The side of the tool and the face of the work were in approximately the same vertical plane.

It seemed desirable to take these photographs at a magnification greater than unity. The magnifications finally used were the result of trial and error. It was found that any magnification between 50 and 100 was sufficiently clear to show the deformation of the metal. The lower magnifications, however, did not bring out all desired details, and the higher ones introduced difficulties of focusing on all particles in the field due to the deformation from the vertical plane in front of the objective. Definite information which would serve as a guide in making the set-up seemed lacking.

Equipment Used in the Tests

The set-up, consisting of a planer on which is mounted the work, tool, microscope, and camera, is shown in Fig. 1. The tube of the metallurgical microscope was mounted in a specially constructed saddle so as to maintain proper alignment with the camera shutter center, but permitted adjustment on the saddle, to and from the work, as different objectives were employed. The objective and eyepiece on the microscope could be changed to suit conditions, although the majority of the pictures were taken with a 16-mm. objective and a $7^1/_2$X eyepiece, which in themselves would give 75 magnifications. A 9 by 12 cm. camera was placed on a saddle back of the microscope with the shutter of the camera close to the eyepiece. A short space was permitted between the shutter and eyepiece to permit slight adjustment of the microscope barrel for the purpose of focusing. A telescopic tube bridged this gap.

The magnification resulting from the microscope objective and eyepiece was modified by the location of the plate of the camera. It was found that, to secure pictures having the same magnification as indicated by the microscope set-up, the plate

---

[1] Director of Engineering Shops, University of Michigan. Mem. A.S.M.E. Orlan W. Boston was born on July 16, 1891, in Nashville, Mich., where he received his early education. He was graduated from the University of Michigan Engineering College in 1913, received a Master's degree in 1917, and the degree of Mechanical Engineer in 1926. After graduation he was engaged at the University of Michigan as instructor in engineering mechanics and mechanical engineering for four years. In October, 1917, he was commissioned in the U. S. Navy and assigned to duty in the Bureau of Ordnance on design and manufacture of submarine mines used in the North Sea blockade. From 1919 to 1921 he was engaged in industrial engineering work for the Cleveland Tractor Company, in Cleveland, as assistant to the vice-president and works manager. In the fall of 1921, he returned to the University of Michigan, where he is now professor of shop practice and director of the department of engineering shop. Professor Boston is the representative of the Society on the Tool Steel Committee of the American Society for Testing Materials, and has been a member of its Special Research Committee on the Cutting of Metals since 1923, serving as Secretary for five years. He is also a member of the American Society for Steel Treating and the Society for the Promotion of Engineering Education. He is author of many papers dealing with the subject of metal cutting.

Contributed by the Machine Shop Practice Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the camera had to be approximatelv $12^1/_2$ in. from the eyepiece. With the plates located at $12^5/_8$ in., the actual magnification of the pictures, as recorded, is 81.25 times. By moving the plate holder toward the microscope eyepiece, the magnification is reduced; by moving it away from the eyepiece, the magnification is increased. This distance of $12^5/_8$ in. between the eyepiece and the plate was larger than that permitted by the camera bellows, so that the shutter of the camera was mounted in a specially constructed frame located back of and in line with the eyepiece. A second frame was constructed to carry the plates. These special frames were then joined by a separate bellows taken from a lantern-slide projector. The camera lens was removed from the set-up.

At first considerable trouble was encountered by lack of proper illumination of the tool and work. Finally, a small 4.5-ampere arc light using $^5/_{16}$-in. carbons was installed, as shown in Fig. 1. It was attached to the tool holder directly over the microscope, so that its illumination was projected on the work at an angle of 45 deg. from the vertical. A yellow filter was interposed between the light and the work. All photographs were taken after dark with lights out. In this condition the image could be focused carefully on the ground glass of the camera before the plate was substituted. A 4 in. diameter hand magnifying glass was used to obtain definiteness on the ground-glass image in focusing.

With the set-up as described, observations could be made on the ground glass during the process of cutting—that is, while the work was being moved into the tool. This set-up was such that the camera could be removed conveniently so that observations could be made directly through the microscope. Many observations through the microscope or on the ground glass have been made. Only specific instances, however, have been photographed.

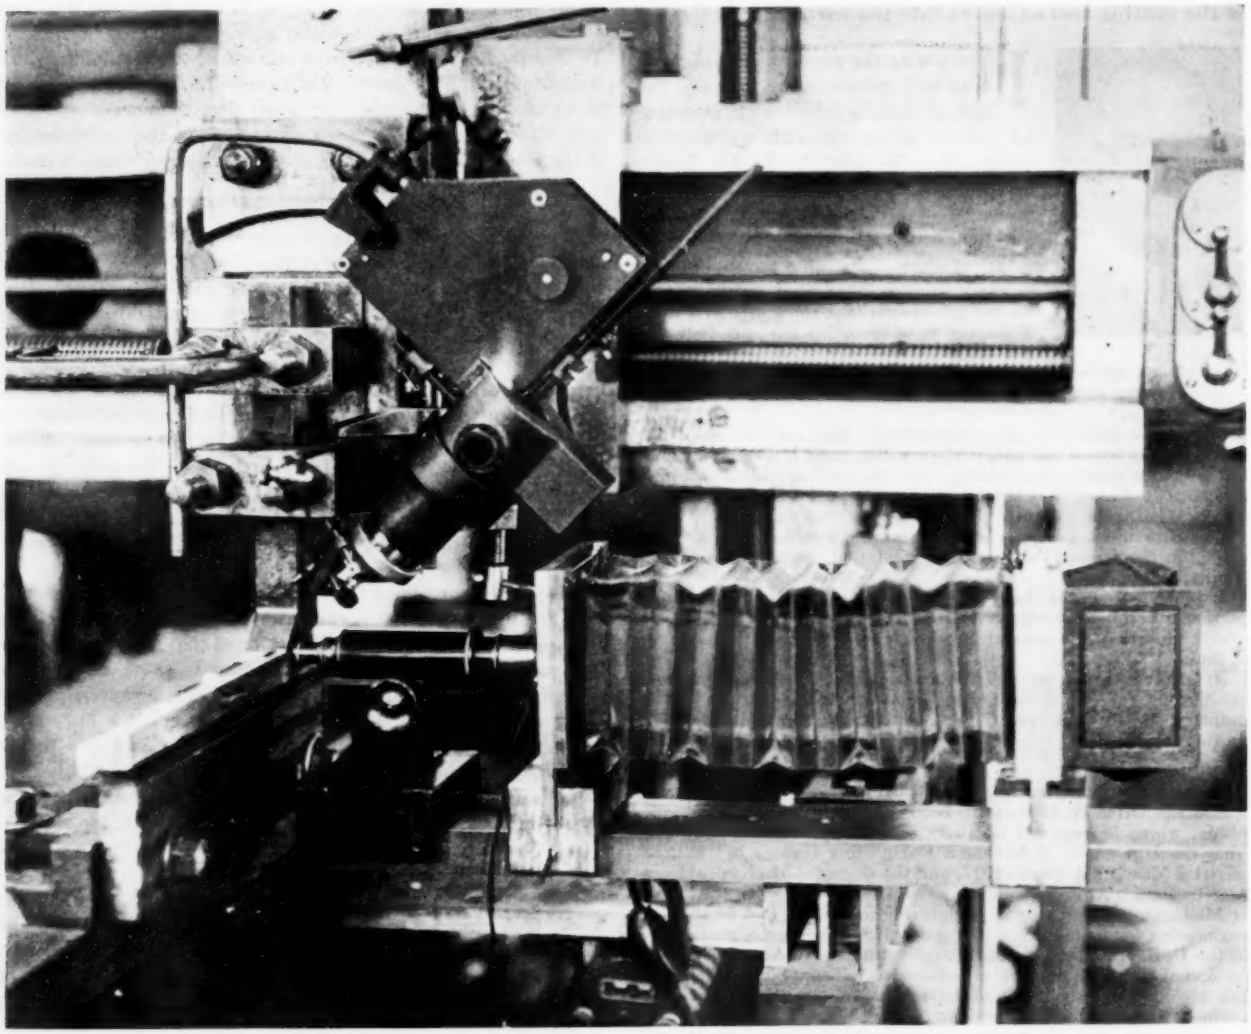

FIG. 1 THE MICROSCOPE AND CAMERA SET-UP ON THE PLANER

A very desirable feature of the set-up, as used, is the possibility of making observations while the tool is cutting continuously, but of course at a very slow speed. The driving wheel of the planer was turned by hand, and the movement of the planer table was recorded on a dial indicator attached to the bed at the end of the table. The operator, in turning the drive wheel, could observe the readings of the dial gage and report continuously to the one making the observations the distance traveled. By this means a great amount of information has been obtained as to the exact formation of the various sections of a chip which might be entirely overlooked in the type of work

where pictures are taken intermittently. In other words, the illustrations recorded in this paper show the chip and tool at a given instant, but in every case observations have been made of the continuous movement of the metal during the formation of the chip from one stage to another—that is, from one picture to another.

Arrangements also have been made for locating a moving-picture machine back of the microscope, so that moving pictures instead of still pictures can be taken to record this continuous cutting process. Some moving-picture films have been prepared, but the results are not altogether satisfactory due to difficulties of illumination and of keeping the object continuously in focus. The scope of this paper is limited to the stationary pictures and the results of observations leading up to these stationary pictures.

(*a*) Combined
(*b*) 1% of impurities

from 1 in. by 2 in. high-speed-steel bars, so that the cutting edge and face of the tool projected beyond the body of the bar. They were ground and lapped to shape so as to present a smooth surface and a keen cutting edge. They were of the end cutting type, similar to a cut-off tool. The clearance angle in each case was 4 deg. The front rake angle, however, was varied to suit conditions of the study and is recorded in the individual tests.

The Feeds and Speeds. In these experiments the feed was

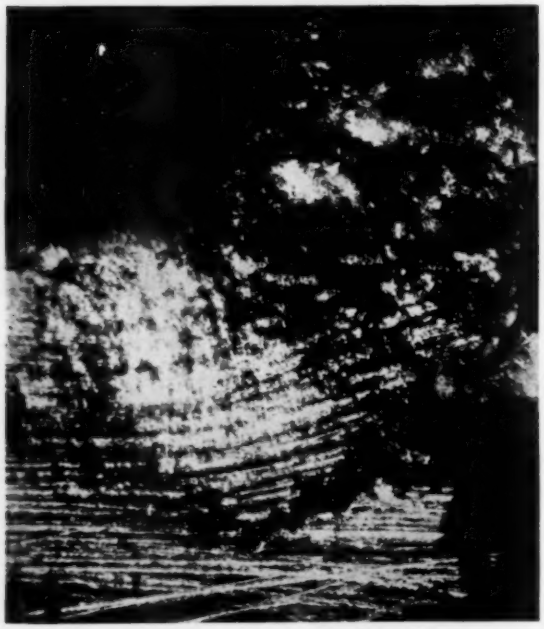

FIG. 6 SHOWING TEAR IN ALUMINUM
(Conditions same as in Figs. 2 to 5.)

obtained by lowering the tool vertically after each chip was removed. The amount of the feed was read from a dial indicator arranged as shown in Fig. 1. Many of these cuts were taken with a 0.005 in. depth, or feed, and some were taken at 0.010 or 0.020 in., as recorded in the individual study.

The speeds used varied considerably. All speeds in this study were obtained by driving the planer by hand so that occasionally a speed of several feet per minute was developed for observation purposes, but when pictures were taken the chip recorded was actually formed at a very slow speed, so that the table could be moved a few thousandths of an inch to the next desirable chip condition.

MATERIALS CUT

Six different materials were studied in this investigation. The chemical analysis of each is shown in Table 1. These materials are as follows:

(*a*) An 0.15 per cent carbon open-hearth steel, bar No. IIII. This bar was fully annealed and produced in a size 4 in. by 6 in. by 4 ft. In tension this steel had a yield point of 20,900 lb. per sq. in. Its ultimate strength was 52,000 lb. per sq. in.; its reduction of area was 65 per cent, and its elongation 40 per cent in 2 in. gage length. In shear the ultimate strength was 39,400 lb. per sq. in. The hardness values were: Brinell, 102; scleroscope, 21; and Rockwell, 45 ($^1/_{16}$ in. diameter ball).

(*b*) A cold-drawn super free-cutting steel for screw-machine work, bar No. 414, 1.078 in. in diameter. This material had an ultimate tensile strength of 86,100 lb. per sq. in. Its Brinell hardness taken on the interior was 207, the Rockwell B scale was 93, and the scleroscope 29.

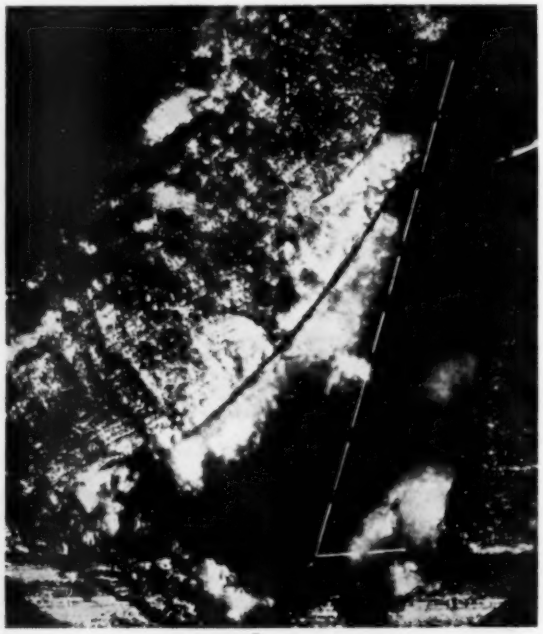

FIG. 7 SHOWING "BUILT UP" NOSE IN ALUMINUM
(Conditions same as in Figs. 2 to 5.)

(*c*) A cast-iron bar No. 11–1, $1^1/_8$ in. round. Its Brinell hardness was 207.

(*d*) No. 12 cast aluminum, 1 in. square, bar Al 12. Its yield point in tension was 18,455 lb. per sq. in.; its ultimate strength was 19,046; its reduction of area was 6 per cent, and the per cent elongation in 2 in. was 1.6.

Its Brinell hardness, with 500-kg. load and 10-mm. ball, was 63, its Rockwell B scale hardness was 77, and its scleroscope hardness was 14.

(*e*) A non-leaded rolled sheet brass $^1/_2$ in. thick, bar No. 26. In tension the yield point was 35,000 lb. per sq. in., ultimate strength 38,000 lb. per sq. in., reduction of area 32 per cent, and elongation in 2 in., 31 per cent. Its shear strength was 35,600 lb. per sq. in. The Brinell hardness for 500-kg. load and 10-mm. ball was 109, and Rockwell B scale hardness was 102, and the scleroscope hardness was 24.

(*f*) A high-speed free-cutting brass (leaded) $^1/_2$ in. square, bar X. The ultimate shear strength was 37,100 lb. per sq. in. The Brinell hardness with 500-kg. load and 10-mm. ball was 105, the Rockwell B scale hardness was 100.5, and the scleroscope hardness was 40–36.

Photomicrographs and various machinability data are shown for these metals in a paper, "Methods of Tests for Machinability of Metals in General, With Results," *Trans. A.S.S.T.*, Vol. 16, Nov., 1929, p. 659.

Observations

Cutting Aluminum. With a set-up of the microscope having a 16-mm. objective and a 7.5-hyperplane eyepiece, and with the camera plate located 12⅝ in. from the eyepiece giving an actual magnification of 81, the observations recorded in Figs. 2–7, inclusive, were taken. A cast-aluminum alloy bar (No. Al-12) was used. A tool having a front-rake angle of 15 deg., which was ground and lapped to give a smooth surface and a keen edge, was used.

A cut having a depth or chip thickness of 0.010 in. was started, and after the tool had moved slowly into the work 0.062 in. it was stopped. The resulting condition is shown in Fig. 2. This position illustrates the instant at which the large section of the chip was sheared loose from the main portion of the metal along the shearing plane extending from the tool point upward

Fig. 8 Tool at Zero

to the left at an angle of approximately 29 deg. from the horizontal, or 76 deg. from the tool face. As the point of the tool advances it gradually accumulates a second chip section similar to the one just sheared off. Repeated observations of the formation of similar sections showed them to vary in size. It was noted that when kerosene was applied to the tool and the work the chip sections were approximately of the same size and that one would be sheared off every 0.023 in. travel of the tool. It can be said that this so-called shearing-off still leaves the chip section attached firmly to the adjacent sections. In other words, there is a continuous chip built up of various sized sections.

Fig. 3 shows the condition of the metal after the tool has been advanced 0.005 in. from that position shown in Fig. 2. In this position the tool point is just beginning to gather up material on its nose. This rotates the last section of chip removed and changes the angle at which the section sheared off from 76 deg. to approximately 90 deg. to the tool face. In Fig. 4 is shown the condition of the metal after the tool has been advanced an additional 0.005 in., which is 0.010 in. advance of that position shown in Fig. 2. Continuous observation between the positions shown in Fig. 3 and Fig. 4 as the tool advanced shows that the section of the chip being formed is built up of a large number of small laminations caused by the tearing and shearing of the metal along the plane of shear, which is approximately

Fig. 9 Tool at +0.005 In.

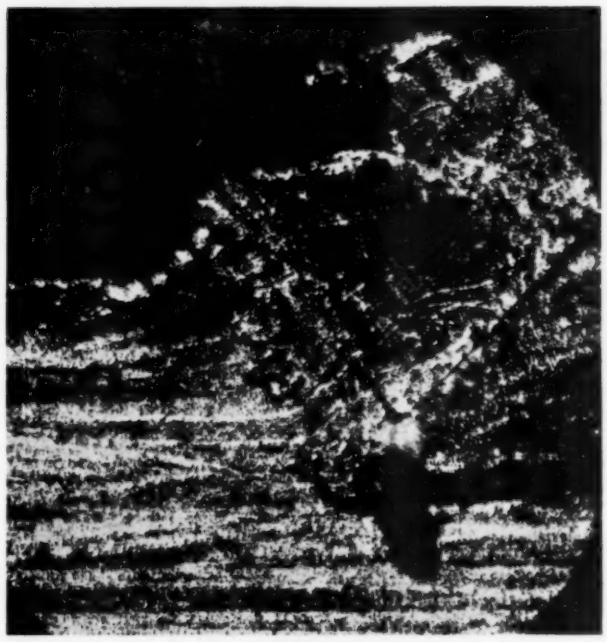

Fig. 10 Tool at +0.010 In.

Figs. 8, 9, and 10 Successive Steps in Formation of a Chip (Cast-aluminum alloy No. 12; depth of cut, 0.010 in.; 45-deg. front-rake tool; actual magnification 110.)

29 deg. to the horizontal. In Fig. 5 the position of the tool is shown after it has been advanced an additional 0.005 in., making a total of 0.015 in. in advance of the position shown in Fig. 2. The section of the chip on the point of the tool shown in Fig. 5

is nearly ready to be sheared as a unit free from the main portion of the material.

In taking preliminary cuts of approximately 0.010 in. in depth on the ridge of the aluminum specimen to prepare it for the

Fig. 11 Tool at +0.015 In.

Fig. 12 Tool at +0.020 In.

0.010 in. depth of cut illustrated in Figs. 2 to 5, inclusive, certain observations were made as recorded in Fig. 6 and Fig. 7. The 15-deg. front-rake tool was started on a cut, and after advancing about $^3/_{16}$ in. along the ridge, it was noticed that a large piece of material ahead of the tool was being torn off by the usual "tear" principle. Fig. 6 shows this tear in advance of the tool point. It shows that the tear goes deeper than the tool point into the metal. This condition did not occur frequently. Whether it is due to some impurity in the metal or to a surface condition is not known.

At another place, in truing up the specimen it was noticed that a built-up portion appeared on the nose of the tool. This condition was duplicated several times, and was finally recorded as shown in Fig. 7, for which illustration the tool has been withdrawn to the right. On another cut the first $1^1/_2$ in. of tool travel showed conditions similar to those represented by Figs. 2 to 5, inclusive. The metal cut poorly, and the chips were formed in sections of unequal shape and size. In moving the tool forward farther to a travel of 2 in., the chip flow became

Fig. 13 Tool at +0.025 In.

FIGS. 11, 12, AND 13 SUCCESSIVE STEPS IN FORMATION OF A CHIP (Cast aluminum alloy No. 12; depth of cut, 0.010 in.; 45-deg. front-rake tool; actual magnification 110.)

smoother and more uniform. The large sections seemed to disappear or become broken up into smaller equal sections, presumably due to a built-up edge which began to appear. Moving the tool still further to a travel of $2^1/_2$ in., a built-up edge became more defined and larger and extended forward into the material in advance of the cutting edge. The slope of this built-up edge just above the point is 50 deg. from the vertical, indicating perhaps that a 50-deg. front-rake angle on the tool is ideal. In moving the tool still further, the chips were removed with less distortion and less defined laminations or shear lines. The metal on the edge of the cut was forced toward the microscope objective and obstructed the view so that this projected mass had to be removed with a scraper. After scraping, the false edge stood out sharply, as recorded in Fig. 7. This was after $3^1/_8$ in. of metal had been cut at a very slow speed. Better to show the false edge, the tool was backed out to the right, leaving the false edge connected with the chip and work. The length of this built-up edge ahead of the tool nose is actually only about 0.016 in. This is 50 per cent greater than the thickness of the chip being removed, however.

It is interesting to observe the slight distortion occurring on the under side of the chip as it rubs over the face of the false edge. From these observations it appears that the material from which the false edge is built is gathered by the point of the tool as it scrapes over the surface after the bulk of the chip has been removed because of the pressure on the face of the tool back of the cutting edge. Fig. 7 does not show clearly what has occurred at the extreme point of the false edge because of a small amount of the cut material which has been forced toward the camera, thereby hiding the nose point.

After the exposures shown in Figs. 2 to 7, inclusive, were taken, kerosene was applied to the tool point and work, and various observations were made through the microscope as the tool was advanced slowly. It was not possible to secure the built-up edge when kerosene was used. The chip itself was removed with less distortion than when cutting dry. It seemed to be made up of thin uniform sections, causing the chip to be more dense and regular than was found in dry cutting. It was possible to observe the oil as it advanced on the face of the work ahead of the tool and even ahead of the material being distorted. This flow of oil would stop when the tool was stopped and proceed uniformly ahead of the tool when it was advanced. It appeared to be drawn into the material of the chip, causing it to be thoroughly saturated and thereby lubricated. It was observed that, as the chip slid over the face of the tool, it seemed to be compressed and the kerosene was squeezed out.

Usually, high rake angles are recommended for the cutting of aluminum. Inasmuch as the front-rake angle of the built-up nose on the 15-deg. front-rake tool, as shown in Fig. 7, was about 50 deg., a 45-deg. tool was prepared and used, as illustrated in Figs. 8 to 13, inclusive. The same camera and microscope set-up was employed, as already described. The work was in a slightly different position, so that an actual magnification of 110 was obtained. The depth of cut was 0.010 in. Fig. 8 shows the 45-deg. tool after cutting a short distance on the cast-aluminum alloy. The position of the tool as indicated is at zero, which is as near to the position at which a section of the chip shears off as could be determined. The definite line of shear is seen extending from the point of the tool to the surface of the work on approximately a straight line which makes an angle with a horizontal of 30 deg. The angle of shear shown in Figs. 2 and 4 when a 15-deg. front-rake tool is used is also shown to be this same angle. In Fig. 9 the tool has been moved

Fig. 14 Tool at Zero

Fig. 15 Tool at +0.024 In.

Fig. 16 Tool at +0.030 In.

FIGS. 14, 15, AND 16 SUCCESSIVE STEPS IN FORMATION OF A CHIP
(Free-cutting screw-stock brass, bar X; depth of cut, 0.005 in.; 15-deg. front-rake tool; actual magnification 100.)

to the left a distance of 0.005 in. from the position shown in Fig. 8. New shear lines are shown extending from the point of the tool to the surface of the material on approximately this same 29- or 30-deg. angle. In Fig. 10, where the tool is shown advanced an additional 0.005 in., making a total of 0.010-in. travel from the position shown in Fig. 8, the new section of chip is shown in formation. The line of shear along which the large section of the chip was moving in Fig. 8 is shown in Fig. 10, changed from 30 deg. from the horizontal to approximately 45 deg. from the horizontal, or at right-angles to the face of the tool. The material in the chip section being formed in Fig. 10, as viewed through the microscope, shows this section, as in previous observations, to be thoroughly broken up by shear and tension. It appears to be in a somewhat honeycombed condition, although this may be only on the surface. The bright spot at the tool point is a small particle of material extending from the field in focus toward the objective. The dark spot below this bright spot is a shadow. In Figs. 11, 12, and 13 the position of the tool is shown advanced in steps of 0.005 in. The section of the chip shown in Fig. 8, which has just been sheared off, is shown at the extreme upper part of the chip in Fig. 13. It has moved about 0.014 in. along the face of the tool from the tool point, or approximately 1.4 times the original depth of cut, while the tool has traveled horizontally 0.020 in. between Figs. 9 and 13. The thickness of chip is 35 per cent greater than the original depth of cut.

From general observations it was concluded at the time the pictures were taken that it was not possible to show a built-up nose on the cutting edge when the 45-deg. tool was used. Close examination of Figs. 12 and 13, however, shows that the front face of the tool is not a straight line, but rather a curve concave upward, indicating perhaps that there is a small layer of metal constituting a built-up edge on the point of the tool. This is shown clearly in Fig. 13. The built-up edge, however, is very small compared with that shown in Fig. 7 when the 15-deg. tool is used. It was noted at the end of each 12-in. cut with the 45-deg. tool in aluminum that a thin film of aluminum adhered to the tool face immediately back of the cutting edge. This may have been the built-up nose seen in Fig. 13. This does not seem to be a factor of high temperature, but rather one of pressure only. This film may increase friction so that the fully developed built-up edge results.

The chip, or built-up edge, along the face of the tool in Fig. 7

Fig. 17 Tool at Zero

Fig. 18 Tool at +0.006 In.

Fig. 19 Tool at +0.012 In.

FIGS. 17, 18, AND 19 SUCCESSIVE STEPS IN FORMATION OF A CHIP
(Free-cutting screw-stock brass, bar X; depth of cut, 0.010 in.; 15-deg. front-rake tool; actual magnification 85.)

resembles very closely that shown in Fig. 13. The actual depth of cut in Fig. 13 is slightly larger than that shown in Fig. 8, due to the digging in of the 45-deg. front-rake tool. The actual depth in Fig. 13 is 0.0107 in., whereas 0.010 in. was anticipated. The tool itself is rotated 2 deg., but this has been taken into account in determining the shearing angles above.

Free-Cutting Screw-Stock Brass. With a 16-mm. objective, a 7.5X-hyperplane eyepiece, the tube of the microscope set at 165, and the plate of the camera placed approximately 14 in. back of the eyepiece so as to give an actual magnification of 100, a free-cutting screw-stock brass, indicated as bar X, was photographed when being cut with the 15-deg. front-rake tool taking a depth of cut of 0.005 in. Three positions of the tool are shown in Figs. 14 to 16, inclusive. In Fig. 14 the tool is shown at the position indicated as zero. At this instant a section of the chip is shown about to be removed from the main portion of the material. The line of shear is a curve extending from the point of the tool to the left, concave upward, until it reaches the upper surface of the material. Watching carefully through the microscope, this line appears to represent a clean-cut surface, and the section of the chip appears to be entirely free from the main portion of the material. The chip, however, is continuous; that is, each section is attached to the next, so that it is not a definite plane of cleavage. A tool travel of several thousandths of an inch was still required before this chip section was completely formed and pushed off in a shape similar to those shown preceding it.

It was repeatedly observed that, with this 0.005 in. depth of cut, a new section was formed each time the tool was advanced to the left a distance of 0.012 in. When the depth of cut was

Fig. 21 Tool at +0.004 In.

Fig. 20 Tool at Zero

Fig. 22 Tool at +0.008 In.

FIGS. 20, 21, AND 22 SUCCESSIVE STEPS IN FORMATION OF A CHIP
(Non-leaded, 1/2-in. thick sheet brass, bar 26; depth of cut, 0.010 in.; 15-deg. front-rake tool; actual magnification 81.)

0.010 in., a section was formed every 0.018 in. of tool travel. These sections for the free-cutting brass were very regular and equal in size. Fig. 15 shows the position of the tool after it has traveled a distance of 0.024 in. from the position shown in Fig. 14. The various chip sections in Figs. 14, 15, and 16 are readily identified. In order to prevent the material of the chip from being pressed over the edge of the tool, the vertical face of the tool is nearer the objective of the microscope than the vertical face of the material being cut. This causes a shadow to be shown below the bottom of the tool from the light above. The white line indicates the tool edge.

Figs. 17 to 19, inclusive, show the free-cutting brass being cut with a 15-deg. front-rake tool, with a depth of cut of 0.010 in.,

but an actual magnification of 85. The cutting conditions are very similar to those having 0.005 in. depth of cut. In both cases the various sections of chip consist of material completely shattered, due to the pressure built up on the tool point. In other words, each chip section consists of a large number of laminated strips or elements which are too numerous to count.

Fig. 23 Tool at +0.012 In.

Fig. 24 Tool at +0.018 In.

Fig. 25 Tool at +0.024 In.

FIGS. 23, 24, AND 25 SUCCESSIVE STEPS IN FORMATION OF A CHIP
(Non-leaded, 1/2-in. thick sheet brass, bar 26; depth of cut, 0.010 in.; 15-deg. front-rake tool; actual magnification 81.)

Fig. 17 shows the position of the tool at zero; that is, a chip section has just been sheared off, and the new section is starting to be formed on the tool point. In Fig. 15 the tool has advanced 0.006 in. to the left and is gathering up the chip section on the face. Fig. 19 shows the tool advanced an additional 0.006 in., in which position the chip section is two-thirds completed, so that an additional 0.006-in. travel of the tool is required before this section is completed.

Non-Leaded Brass. Figs. 20 to 25, inclusive, show six positions of a 15-deg. front-rake tool when taking a cut 0.010 in. deep in the 1/2-in. thick non-leaded sheet brass, bar 26. Fig. 20 shows the tool at a position which is called zero. Each following figure shows the tool advanced an additional 0.004 in. The formation of each chip section of non-leaded brass appears to be very similar to that for the leaded brass. It was observed, however, that the various chip sections were not uniform in shape or size, nor were they as distinctly identified as in the case of the leaded brass. While there were definite shear lines visible, one section seemed to be pressed quite firmly into the next section. In these illustrations, Figs. 20 to 25, inclusive, the face of the tool being photographed projected slightly nearer the objective than the face of the material, in order to prevent the flow of the material over the edge of the tool and thereby obstruct its view. For this reason there is a slight shadow at the bottom of the tool. Due to the pressure of the chip on the tool face, the chip material was forced toward the objective and appears as light spots in the illustrations. Through the microscope the deformed area shown dark immediately ahead of the tool point is seen to consist of almost an infinite number of laminations, so that the material seems to be very uniformly crushed and sheared. These lines of shear are definite lines when viewed through the microscope, but in the illustrations these lines are not sharply defined, but as a group appear as a dark area. They curve concave upward from the tool point to the surface, making an angle with the horizontal smaller than for free-cutting brass. The six illustrations show progressively how the chip is formed as the tool is moved to the

left in six equal steps of 0.004 in., making a total of 0.024 in. travel. There appears to be no uniformity in these chip sections, and the chip as a whole appears more continuous than is the case with the leaded brass.

Cast Iron. Using the set-up as previously outlined to give a magnification of 81, a depth of cut of 0.010 in. on a cast-iron bar (No. 11–1) was first studied, but it was thought that the observations lacked definiteness, so that a depth of 0.020 in. was resorted to. There appeared to be no relation between the travel of the tool and the formation of any type of chip section; so five pictures have been taken, between each of which the tool has traveled 0.005 in., except that 0.010 in. travel was taken between Figs. 27 and 28. All of these pictures indicate that the bulk of the chip of cast iron is removed by virtue of a pressure built up on the face of the tool somewhat back of the cutting edge at a distance not greater than the depth of cut. The cutting edge itself seemed to do little work and that was in scraping over the surface from which the chip had been removed.

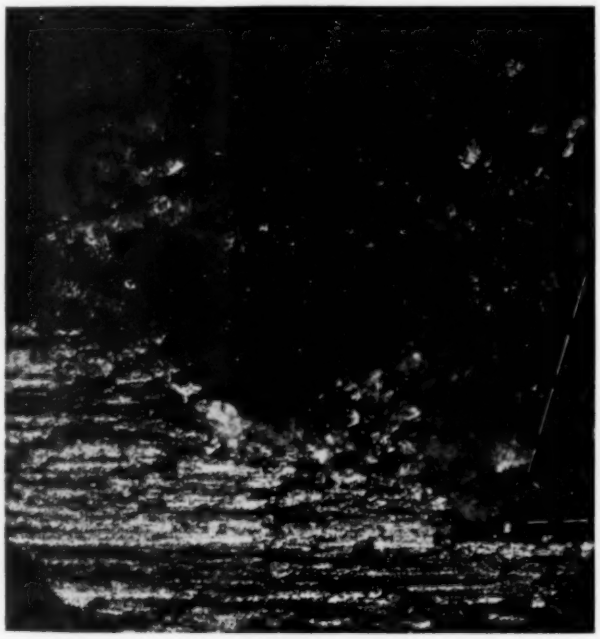

Fig. 26 Tool at Zero

Also, instead of removing the chip in large sections with little distortion, it appeared in most of these pictures that the cast iron was completely broken up into fine particles of no particular shape or size. No shear lines were observed. The cast-iron dust was blown away each time before the pictures were taken. Fig. 30 shows one illustration after the tool has advanced 0.005 in. from the position shown in Fig. 29, in which a large piece of cast iron is being removed as a solid body. The crevice to the left of the tool point extending horizontally is apparently the only fracture in this case. It may be that this particular formation of chip is due to a defect or an unusual condition of the material along the surface which failed. It has been observed that long chips of cast iron may be formed; the slightest touch, however, will cause it to crumble.

Free-Cutting Steel Screw-Stock. Figs. 31 to 36, inclusive, show six positions of the 15-deg. front-rake tool when cutting a free-cutting steel screw stock, bar 414, when taking a depth of cut of 0.010 in. The actual magnification is 81. In this case pictures were taken at each 0.005-in. travel of the tool. Fig. 31 shows the tool at zero—that is, at a starting point which was arbitrarily selected as the tool was in the process of cutting. The tool point is at the lower right hand of the lowest shear line and is just visible in the illustration. The shear line extends from the tool point in almost a straight line to the surface

Fig. 27 Tool at +0.005 In.

Fig. 28 Tool at +0.015 In.

FIGS. 26, 27, AND 28 SUCCESSIVE STEPS IN FORMATION OF A CHIP (Cast iron bar 11–1; depth of cut, 0.020 in.; 15-deg. front-rake tool; actual magnification 81.)

making an angle of about 13 deg. These lines of shear appeared to be outstanding at the start, but due to the pressure of the chip on the face of the tool and the resultant pressure on the material

being cut, the chip was compressed as it moved along the tool face, which caused these lines to become small, and in most instances practically losing their identity. In Fig. 31 one of these shear lines is shown at the start. In Fig. 32, after the tool has traveled 0.005 in., the shear line is still to be seen, but the material below the shear line to the left is being compressed and sheared into small laminations. In Fig. 33 the shear line is still clearly seen, but has traveled slightly along the tool face, and the material below is shown distorted. In Figs. 34, 35, and 36 the formation of the chip below this line of shear is shown. in which there are no major lines, but the metal itself shears and bends as it is being compressed on the tool point and forced against the portion of the chip above. The material ahead of the tool point is being distorted, making approximately a straight line at an angle of 20 deg. with a horizontal in Fig. 34, 24 deg. in Fig. 35, and 25 deg. in Fig. 36. This angle seems to vary at

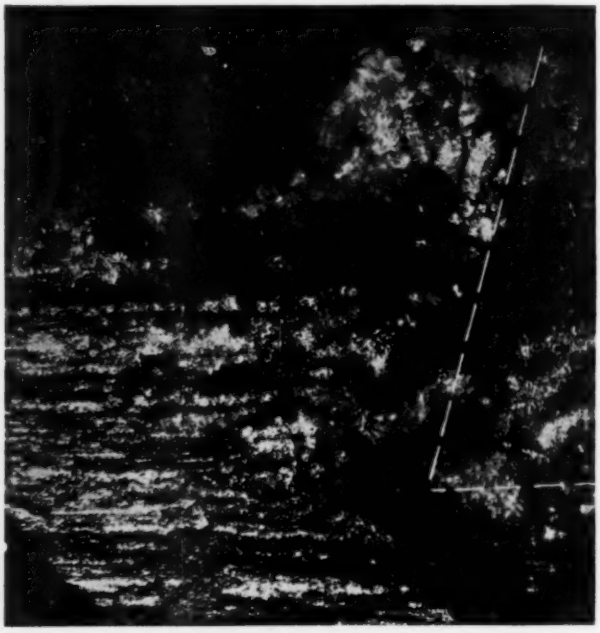

Fig. 29 Tool at +0.020 In.

Fig. 30 Tool at +0.025 In.

FIGS. 29 AND 30 SUCCESSIVE STEPS IN FORMATION OF A CHIP
(Cast-iron bar 11–1; depth of cut, 0.020 in.; 15-deg. front-rake tool; actual magnification 81.)

different positions. It was observed for this material that while the chip was being formed it did not bulge toward the objective of the microscope as much as low-carbon steel.

After making many observations through the microscope during the formation of this material into chips in a dry condition, lard oil was applied from a lubricating can to the point of the tool and adjacent work. It was noticed that the chip was formed with less distortion. The chip seemed to be smaller and more dense. No sharply defined lines of shear between sections of the chip could be observed as when cutting dry, as shown in Fig. 33.

Low-Carbon Steel. It was difficult to get clear observations when cutting the low-carbon steel because of its tendency to bulge when being compressed by the tool. This bulging caused the material being deformed to move out of the plane of focus. In making such observations, the microscope was focused at different times on the tool, on the chip, on the material before being cut, and on the material at the point of rupture ahead of the tool. This last point seemed to be most interesting, so that most of the photographs were taken with this point in focus. In Fig. 37 is shown a chip 0.005 in. in depth being cut by a 15-deg. front-rake tool. The magnification is 100. The vertical lines on the original surface of the material were cut 0.010 in. apart on a dividing engine so as to make it possible to compare directly the various distances in the illustration. It is seen that the material is sheared or pushed to the left from the tool point seen in the lower right-hand corner, on a curved line starting at an angle of approximately 0 deg. and ending at 40 deg. above the horizontal. The point at which this shearing surface intersects the upper surface is at the point where the chip begins to bend. The top surface is pushed to the left by the previous cut. The actual length of the line of shear from the tool point to the top surface of the metal is about 0.015 in., or about 2.5 times the depth of the cut.

Figs. 38(*a*) and 38(*b*) show a chip being removed by a 30-deg. front-rake tool. In Fig. 38(*a*) the magnification is 65.5, and the depth of cut is 0.005 in. The line of shear from the tool point to the surface of the chip appears to be a straight line making an angle of about 37 deg. above the horizontal. The material is distorted when about 0.010 in. ahead of the tool point as against 0.015 in. in the case of the 15-deg. front-rake tool. In Fig. 38(*b*) the same 30-deg. front-rake tool is used, but the depth of cut is 0.015 in., and the magnification is 87. The line of shear ahead of the tool point, between the solid material and the chip being formed, is about 10 deg. It appears, then, that with an increased depth of cut, the material ahead of the tool is distorted in greater proportion. In Fig. 38(*a*) there appears to be a definite tear line in front of the tool point. In most of the observations through the microscope, this tear was not visible, so that the tear indicated may be but the result of shadows in the illustration. The vertical lines scratched on the material below the tool are spaced 0.010 in. apart and are visible in Fig. 38(*b*) on the surface of the chip where they are compressed to practically half that distance apart.

Figs. 39, 40, and 41 show the same low-carbon steel being cut with a 45-deg. front-rake tool when the depth of cut is 0.010 in. Fig. 39 shows the tool at the starting point called zero, which is an arbitrary point selected after the tool had cut some distance. Fig. 40 shows the tool after it is advanced 0.010 in., and Fig. 41 after it has advanced an additional 0.005 in., or a total of 0.015 in. from that position shown in Fig. 39. Various points on the chip and surface of the material may be identified in the three illustrations. The tool point is seen in the lower right-hand corner. The lines of shear, or those lines on the surface of the material indicating failure due to the pressure on the tool, are readily seen in the three illustrations at an average of from 25 to 30 deg. from the horizontal. They vary with the position of the tool, other conditions being equal. With this high rake angle, the chip seems to be removed with less distortion and with less increased thickness than with smaller front-rake angles.

Fig. 31 Tool at Zero

Fig. 42 shows a 60-deg. front-rake tool taking a depth of cut of 0.005 in., when magnified 87 times. A 0.010 in. depth of cut caused the tool cutting edge to fail by breaking off so that the lighter cut was used. As in the case of the 45-deg. tool, the ratio of the depth of cut to chip thickness has increased but little.

It appeared that the cutting edge of the tool was rather blunt. This may be due to the high magnification or to a poorly ground tool, or it may be due to the material built up on the cutting edge, or even material covering the cutting edge in the field of vision.

The formation of the chip, however, seemed to be similar for all values of rake angle. The lines of shear were about 60 deg. from the vertical. There is more rubbing on the tool face for lower rake angles. Fig. 42 shows practically no contact between the face of the tool and the chip other than at the point of the tool.

In general, looking through the microscope as the tool is advanced slowly into the work, the lines of shear extending from the tool point to the surface of the work at an average angle of 30 deg. from the horizontal are rotated as the chip passes the tool point, due to the pressure of the material being formed into a chip at the tool point. Also, as the chip slides along the face of the tool, the bottom surface of the chip in contact with the tool face is held back, presumably by friction,

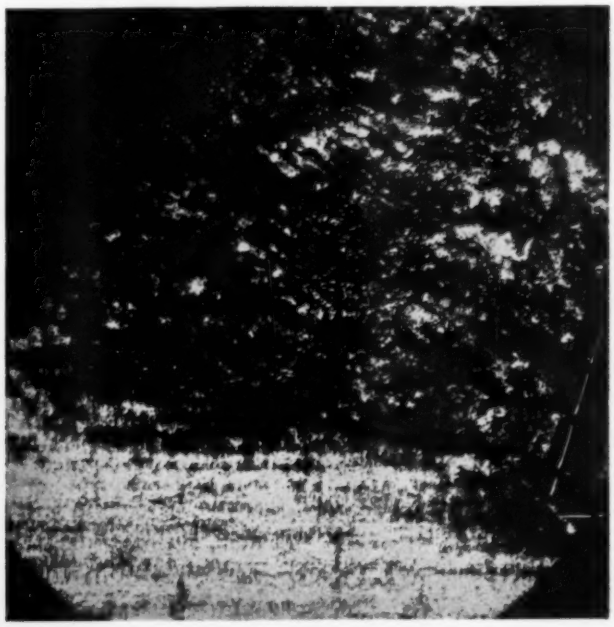

Fig. 32 Tool at +0.005 In.

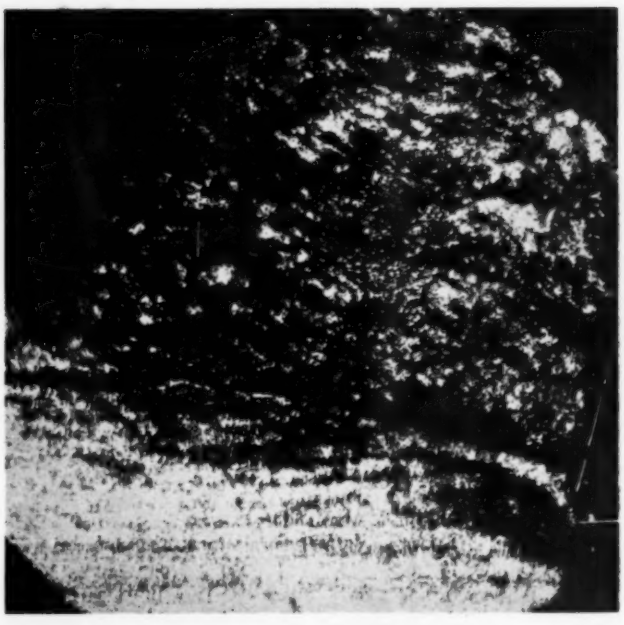

Fig. 33 Tool at +0.010 In.

FIGS. 31, 32, AND 33 SUCCESSIVE STEPS IN THE FORMATION OF A CHIP

(Free-cutting steel screw-stock bar 414; depth of cut, 0.010 in.; 15-deg. front-rake tool; actual magnification 81.)

which may account for the rough torn surface on the bottom of the chip. This condition is shown clearly in Figs. 31 to 36, in which free-cutting steel screw stock is cut, while the opposite is true when cutting cast aluminum, as shown in Figs. 8 to 13, inclusive.

Influence of Cutting on Crystalline Structure of Low-Carbon Steel

A photomicrographic study was made of a chip of the same 0.15 per cent open hearth, annealed carbon steel. A cut 0.020 in. deep with a 30-deg. front-rake tool was made for a length of approximately 2 in., when the cutting was stopped, the tool was withdrawn, and the section of the metal forming the chip about the tool point was cut out. This section was cast in Wood's (bismuth) metal, after which the surface was polished and etched. Fig. 43 shows this section when magnified 30 times. The structure of the chip as well as the uncut material about the tool point is seen. Fig. 44 shows an enlarged view (100 magnification) of the section about the tool point. A built-up nose is shown. The exact location of the tool point is not known, although it is believed to be dulled sufficiently to permit the portion of the built-up nose below *B* to ride on the cutting edge. The tool had previously been very carefully ground and lapped, however. Unfortunately, to the right of *B* an inclusion appears which to some extent handicaps the analysis. The small ribbon appearing on the under side of the chip is believed to be a built-up nose extending for some distance along the face of the tool above the cutting edge.

Fig. 34 Tool at +0.015 In.

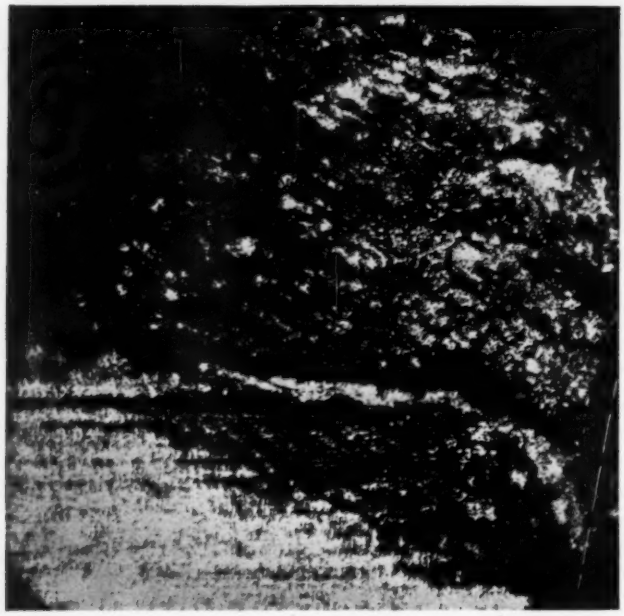

Fig. 35 Tool at +0.020 In.

After examining the specimen itself under the microscope at from 100 to 700 magnifications, the following conclusions were reached: That portion of the nose bearing on the horizontal surface just cut is integral with the main portion of the metal. No lines of cleavage were visible. The actual tip of this built-up nose is firmly embedded in the metal ahead of the tool point. From the actual tip of this nose a crack appears extending parallel to the face of the tool between the ribbon and the main portion of the chip. The ribbon appears to be completely separated from the chip, and the chip appears to be sliding over the upper surface of the ribbon. The ribbon itself, of which only two-thirds is visible in Fig. 44, the upper one-third projecting into space as seen in Fig. 43, appears to have a structure quite different from that of the main chip. The grain size is larger and does not give the appearance of having been compressed unless equally on all sides. It is not laminated parallel to the tool face.

Fig. 36 Tool at +0.025 In.

Figs. 34, 35, and 36 Successive Steps in the Formation of a Chip (Free-cutting steel screw-stock bar 414; depth of cut, 0.010 in.; 15-deg. front-rake tool; actual magnification 81.)

It appears in Fig. 44 that there is a definite connection between the ribbon and the main portion of the chip at *B*, which is that section containing the inclusion. A careful examination, however, at higher magnifications shows this to be not the case, but rather the ribbon is quite independent of the chip from a point adjacent to the built-up edge.

The chip itself appears to be sheared into elements extending from the point of the built-up nose along a straight line upward and to the right, making an angle of 42 deg. with the horizontal. As the tool advances, this metal being formed into a chip slides over the built-up ribbon, causing the under surface of the chip to be retarded on account of friction. These original straight lines of shear at 42 deg. with the horizontal, therefore, are gradually distorted so that their lower ends are turned toward the tool point and become almost parallel with the tool face at the point of contact with the ribbon. This same condition is shown by Herbert (Ref. 26) and others. It is curious, however, that an examination of the under side of many continuous chips produced in this way, instead of showing the ends of these various elements pointing toward the tool point (that is, toward the original metal), shows file teeth or edges pointing away from the tool point. It is true, however, that the file teeth formed on the under side of the chip point away from the tool

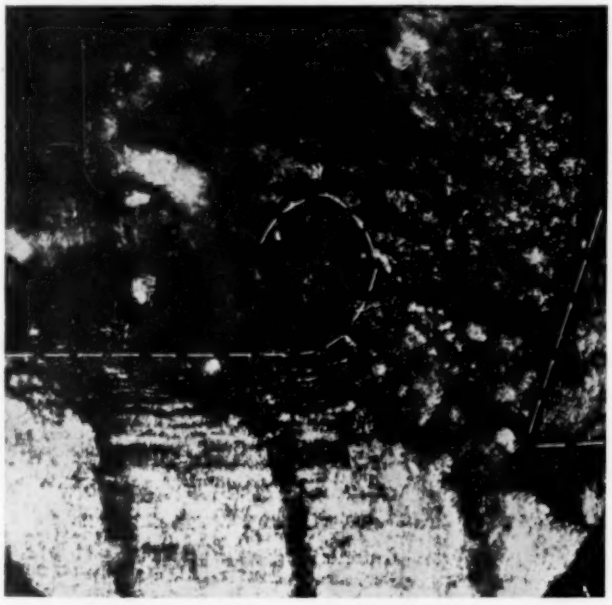

FIG. 37 LOW-CARBON STEEL
(15-deg. rake tool; 0.005 in. depth of cut; actual magnification 100.)

point, but the chip elements themselves are bent under so as to point toward the tool point.

Another point of interest is to note the amount of distortion below the newly cut surface. The various crystals have been dragged to the right by the built-up nose. At the same time they have been compressed. It is seen that the crystals are elongated—that is, flattened and turned parallel to the newly cut surface to a depth below the newly cut surface of approximately 0.006 in. It is also seen that the material immediately ahead (that is, to the right of the built-up nose in Fig. 44) is compressed clear to the edge of the picture, which is approximately 0.017 in.

Fig. 45 shows a view at 100 magnifications of the outer surface, shown in Fig. 43, of this low carbon steel chip. The letters *A* and *C*, in Fig. 45, may be readily identified with similar letters in Fig. 43. While the shear lines from the point of the built-up nose intersect the upper surface of the metal at a point *A*, it is believed that distortion occurs as far to the right as point *C*. The distance from *A* to *C* is approximately 0.020 in. It might be argued that the distortion below *C* is due to the previous cut. This may be so, but several previous very shallow cuts were taken purposely to avoid this difficulty.

A BRIEF REVIEW OF SIMILAR WORK OF OTHER EXPERIMENTERS

C. F. Roby (Ref. 11) has described his observations of successive steps in the formation of a milling-cutter chip. A

FIG. 38(*a*) LOW-CARBON STEEL
(30-deg. rake tool; 0.005 in. depth of cut; actual magnification 65.5.)

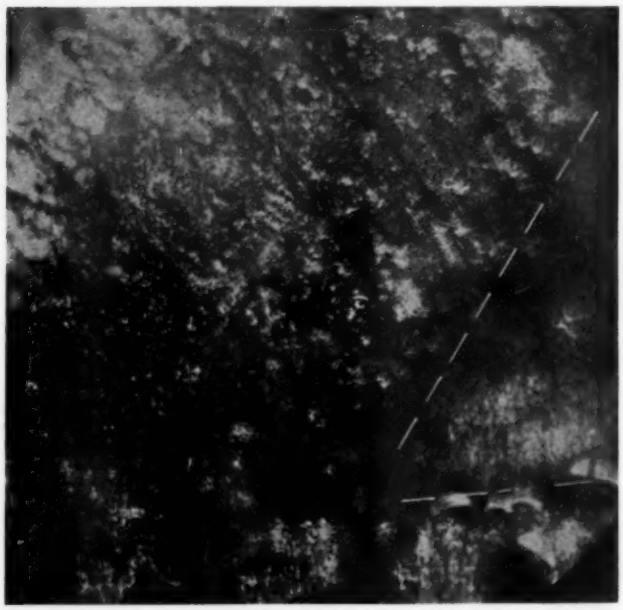

FIG. 38(*b*) LOW-CARBON STEEL
(30-deg. rake tool; 0.015 in. depth of cut; actual magnification 87.)

cutting speed of 1.5 ft. per min. was obtained. Paraffin and lead were first employed as test materials. The former crumbled under the pressure of the cutter, and the latter proved to be too soft for experimental purposes. Babbitt metal was found to be satisfactory, and a comparison of chips from this alloy and from the steel showed that the cutting action was the same in both cases. Tests were made with rake angles of the

milling-cutter tooth ranging from zero to 20 deg. Roby concluded that the tool compresses the metal until the load is sufficient to shear a chip off in sections. After this slip or shear of the section has taken place, the point of the tool slides over the surface and gives it a finish. This statement is contrary to those of Herbert, but substantiate many of the observations of the author.

Roby states further that while the metal is being compressed it is deformed and spreads out over the face of the tool. If a heavy cut is taken this lateral strain becomes great enough to split the chip before it shears off. A small rake angle on the tool has a tendency to cause the same condition. After one chip section is sheared off, another begins to form, and the preceding section slides over the tool and away from the work. This slip action is accompanied by a slight turning action, and the two combined cause the tool to wear away on the face just back of the cutting edge. The size of the chips depends upon the kind of metal cut, the depth of cut, and the cutting speed. In the case of a soft ductile metal such as steel, the section of chip which is sheared off does not drop away, but is held in place by properties inherent in the metal, and a succession of these chips curls off and forms a long shaving. Cast iron, how-

ever, acts differently, the chips dropping away directly as they are sheared off. Roby states that there was no crack preceding the point of the tool—that is, no tear type of chips. This agrees substantially with the observations of the author. The angle at which shear takes place ranges between 24 and 31½ deg. with the horizontal, but varies with the material, the depth of cut, and the rake angle of the tool. The author found many of these angles to be as low as 10 deg. Roby states that this angle increases as the cut deepens and as the rake of the tool is increased. As the angle increases, the area of shear becomes less, and therefore the shearing stress becomes smaller. This may account for the fact that a thick chip is removed with less power than a thin one. He states further that this is probably true only up to the point at which the chip begins to split and crumble, after which power is wasted in deforming the chip. It is to be noted that all of the illustrations shown by Roby indicate that the chip as formed consists of very definite sections. These sections seem to be built up on a ribbon which furnishes the contact with the face of the tool.

William Rowell (Ref. 7) reports that the built-up edge forms almost instantly after cutting starts and that high-speed-steel tools are particularly prone to develop the built-up edge, which explains in a way why high-speed steel is not as satisfactory as carbon tool steel for finishing tools. Inasmuch as the tools used by the author were all high-carbon-steel tools, he is not able to comment on this feature. A few years ago, however, an attempt (Ref. 21) was made to note differences in forces required to cut a given metal under conditions which were constant, except that one tool was of carbon steel and the other of high-speed steel. No differences in forces could be detected.

Rosenhain and Sturney in their "Report on Flow and Rupture of Metals During Cutting" (Ref. 17) concluded that chips were of three different types—namely, tear, shear, and flow. They report that in the tear type of chip the chip is separated from the stock by means of a tear running well ahead of the tool point and "the whole of the chip moves outward relatively to the tool until rupture occurs; then the tool impinges upon fresh metal. This action is likely to result in considerable wear on the cutting edge." The author's Figs. 6, 11, and 30 indicate this tear type of chip. They report further that when the flow type of chip is formed, the metal leaves the stock in a ribbon which is more or less unbroken. The deformed zone or built-up edge is stationary so far as motion relative to the tool is concerned and acts as a protection to the nose of the tool. The actual cutting action proceeds from the apex of the deformed zone (see Figs. 7 and 47). So long as the chip continues to come off in a continuous ribbon or breaks from a point distant to its root, the only wear on the tool will occur on a point some distance from the nose. This wear will be greater with small top-rake angles (compare Figs. 7 and 13).

They report that the shear "type of chip is produced under conditions intermediate between those producing the tear type on the one hand and the flow type on the other; for example, a small depth of cut combined with a small top-rake angle." Figs. 2 to 5 and 14 to 17, inclusive, illustrate this type of chip.

FIG. 44 ENLARGED VIEW AT TOOL POINT OF FIG. 43
(Actual magnification 100.)

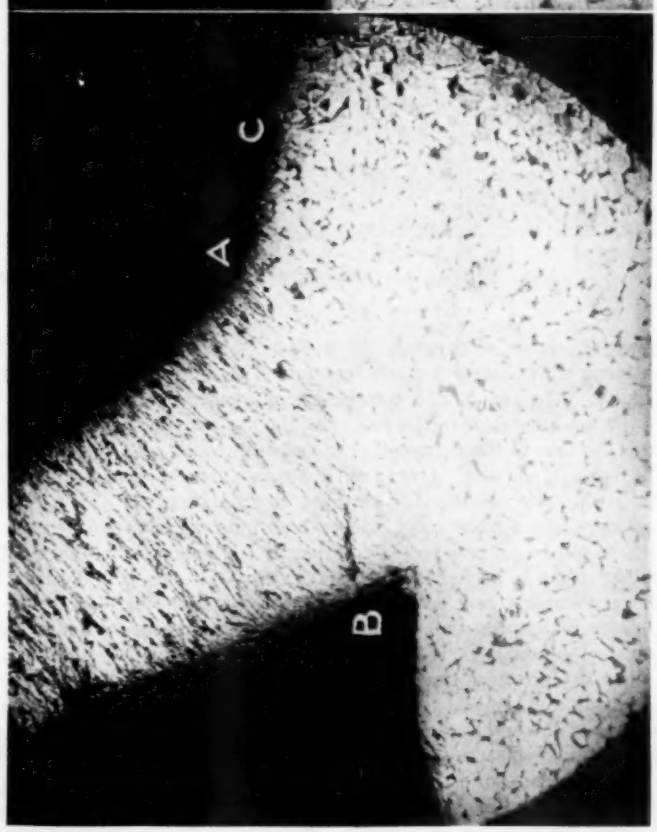

FIG. 43 POLISHED AND ETCHED SECTION OF A CHIP
(Cut by an end-cutting 30-deg. front-rake tool with no side rake; material is 0.15 per cent carbon oil-hardened and annealed steel; depth of cut, 0.02 in.; actual magnification 30.)

It is further reported that the built-up edge on the cutting tool, which has been the subject of so much discussion, appears by microscopic examination as not produced by particles scraped from the work which form themselves into a solid mass between the work, chip, and nose of the tool.

"The material in the zone is strongly deformed. The structure is sufficiently well defined to indicate that it certainly has not been deformed by the building up of any considerable number of separate particles. The continuity of the metal in this severely deformed zone with the metal of stock and chip can further be demonstrated by a simple experiment. Annealing causes the rapid recrystallization of deformed metal and the reestablishment of normal microstructure. It is well known, however, that such a new microstructure is never continuous; that is, the structural constituents do not cross the finest crack, nor even the line of a weld. The deformed zone in the present experiments, however, shows after annealing a microstructure perfectly continous with that of the adjacent metal, thus proving real continuity. The area of the deformed zone appears to be related to the top-rake angle of the tool. As the top-rake angle is increased, the area of the deformed zone decreases, until with a top-rake angle of 30 deg. it entirely disappears, for brass. If this deformed zone consisted of particles scraped from the work, its disappearance when using a tool whose top-rake angle was 30 deg. would be an unexpected coincidence. The conclusion therefore seems to be indicated that the deformed zone is produced by crumpling and deformation of the metal during the first stages of cutting, the amount of such crumpling depending on the top-rake angle of the tool."

The author has previously explained in reference to Fig. 44 that the built-up nose appears, at all magnifications up to 700 to be continuous on the bottom and along the front of the rectangular section immediately about the point with the adjoining metal. It also appears perfectly clear that the ribbon extending from the nose along the face of the tool underneath the chip is distinctly separated from the chip proper.

In watching the growth of the built-up edge of aluminum as illustrated in Fig. 7, it first appeared as a built-up edge similar to the one shown, but much smaller, and quickly grew in size to that shown which, for the tool shape and size of cut, appeared to be the normal, from which no further divergence occurred. Obviously, Rosenhain's statement as to the continuity of material between the chip and built-up nose agrees with those observations of the author immediately at the built-up nose point, but not beyond this point. The author cannot justify the so often-used term "weld" in connection with this built-up edge. Heat is unquestionably created as the metal is deformed, but many observations where the metal is not even colored show results similar to those when the metal is colored. If welding did occur, certainly the metal would show it. Rosenhain shows in his Fig. 16, for brass, that the chip is not the result of welding because "the built-up nose is continuous, and the structural constituents do not cross the finest crack, nor even the line of a weld."

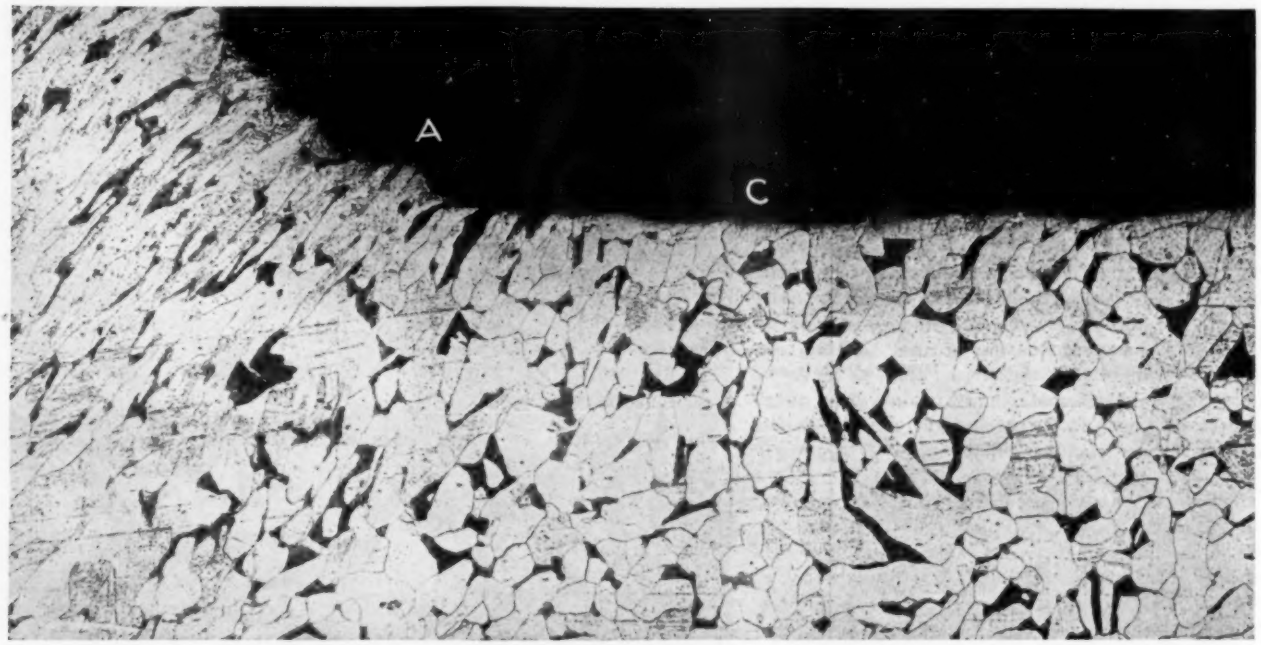

FIG. 45 ENLARGED VIEW OF OUTER SURFACE OF CHIP FORMED IN FIG. 43
(Actual magnification 100.)

Coker has shown (Ref. 14) that when cutting a mild-steel plate taking a shaving of 0.010 in. in thickness with a tool having a front-rake angle of 30 deg. and a clearance of 3 deg., the distorted area in front of the tool has a boundary, when cutting dry, extending from the point of the tool to the surface considerably ahead of the tool along a concave upward curve. When a trace of lubricant is introduced, this boundary line, or shearing plane, is considerably shortened and becomes practically a straight line. The author did not observe this particular condition, at least not in this exaggerated form. It was observed, however, that the chips were more compact and slightly less distorted.

Klopstock (Ref. 15) concludes that there is no doubt that the process in turning is the same as that in planing, notwithstanding the fact that chips from the two processes were taken at entirely different cutting speeds. The surfaces from which the chips were cut also show similar appearance. Klopstock photographed successive steps in the formation of chip elements

and concluded that the process of cutting might be divided into four parts: (1) the initial compressed material in front of the tool, causing the tool to get its first new grip on the work piece after a chip has been broken off; (2), a slight initial tear is caused between the main part of the work piece and the material which is to form the next chip element; (3) the material which is to form the next chip element is compressed and bulges on the lip surface; (4) a tear is caused between this material and the main work piece. This tear is generally not complete but, with the exception of cast iron and similar materials, a certain connection remains between the individual chip elements. He concludes that this conception explains the oscillating form of chip pressure curves obtained by Nicolson and others. In these curves the points of maximum pressure represent the moment of maximum compression of the chip elements, while the lowest points immediately succeeding the points of maximum represent the instants after the chip elements have been broken off.

Codron's conception of the formation of a chip is also reproduced, which agrees substantially with that of Klopstock. The author believes that these conceptions are substantially

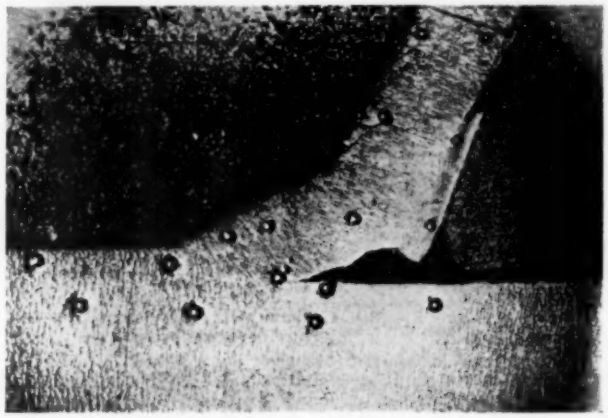

FIG. 46(a) FIRST STAGE IN FORMATION OF "BUILT-UP" EDGE IN STAINLESS IRON B
(After E. G. Herbert. Actual magnification 10.)

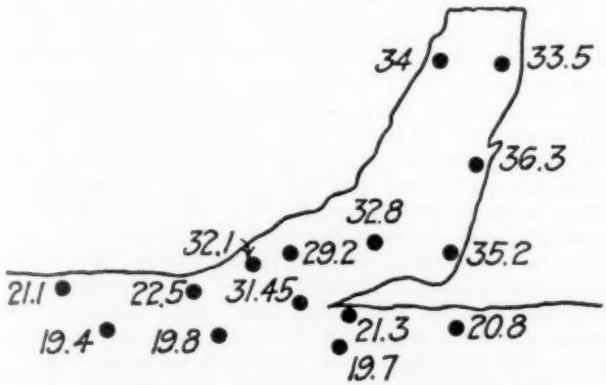

FIG. 46(b) DRAWING FROM FIG. 46(a)
(After E. G. Herbert.)

true, but that the shearing action referred to is more continuous than that appreciated by Klopstock or Nicolson; that is, that each individual chip element or section in itself consists of a large number of laminated sections. Klopstock further reports that the subdivision into chip elements is not always noticeable. Some chips may consist partly of clearly separated chip elements and partly of rather continuous sections, in which the individual chip elements can hardly be recognized. This agrees with the observations of the author.

Mr. E. G. Herbert has reported (Ref. 26) on a detailed study made of the cutting action of roughing tools having a top-rake angle of 20 deg. It was found that "the implement which actually does the cutting in such cases is not the tool, but the structure known as the "built-up edge," an intensely hard body roughly triangular in section formed by the welding of successive layers of material derived from the zone of the cut and deposited on the point of the tool so as to protect it from contact with the

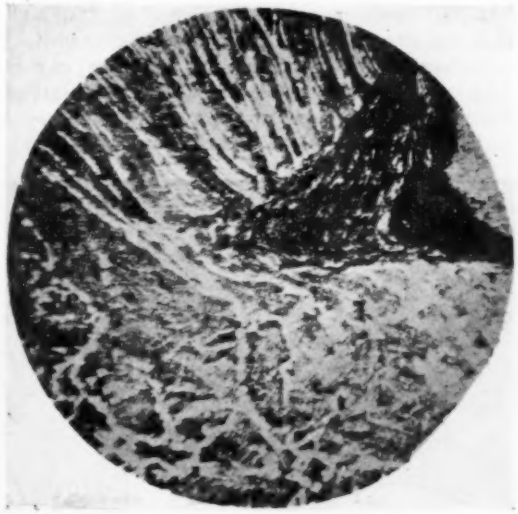

FIG. 47 "BUILT-UP" EDGE IN MILD STEEL
(After E. G. Herbert. Actual magnification 50.)

material it is ostensibly cutting. It is reported that the first stage in the formation of a built-up edge consists in dragging a layer of steel from the under side of the chip through the intense frictional resistance between the chip and the top surface of the tool over which it is constrained to flow. This thin layer separates itself from the chip and attaches itself to the tool, and a second layer, similarly formed, "welds itself onto the top of the first, this process being repeated until the complete edge is built up of innumerable layers welded together." The author has often found this to be the case, except that he does not like the word "weld." Fig. 44 shows an exceptional case.

Fig. 46(a) and Fig. 47 show, respectively, Herbert's conception of the first stage in the formation of the built-up edge and the built-up edge after the tool has cut continously. Unfortunately, Herbert's original paper (*Trans. A.S.M.E.*, 1926, Vol. 48) shows that Fig. 46 applies to stainless iron, B, whereas Fig. 47 applies to mild steel. There may, therefore, be some doubt as to this conclusion. Figs. 2 to 7, inclusive, for aluminum, in this paper, confirm this conclusion. Herbert reports that "owing to the steep slope of the top face of the tool, the built-up edge is not able to find a permanent resting place, but slips off the tool as soon as it has been formed. It is carried away by the chip, from which it has never become completely detached and can be seen as a series of ridges on the under side of the chip." It is reported that some of the temporary edges were formed and discarded not less than fifty times a second. It is reported, further, that the structure of the edge is continuous with that of the chip, as originally pointed out by Rosenhain and Sturney (Ref. 17).

Herbert further reports that the cutting speed has a great deal to do with chip formation. Photographs of cut and polished

sections through the cutting edge, taken at the lowest speed of 7.45 ft. per min., at a standard speed of 61 ft. per min., and at the highest lathe speed of somewhat less than 165 ft. per min., are given in Figs. 48, 49, and 50, respectively. These were taken in turning a mild steel bar (8X) with a feed of 55 turns per inch and a depth of 1/4 in., with a 35-deg. top-rake tool having a 7-deg. side clearance. This top rake was actually side rake on a side-cutting tool. The conclusions drawn from these speed tests were that, with the standard speed of 61 ft. per min., the amount of distortion, judged by the thickening of the chip, was less than at higher or lower speeds, while the average hardness of the chip was also less at this standard speed of 61 ft. per min. At the three lower available speeds (7.45, 12.2, and 18 ft. per min.), the chip formation was reported as abnormal. There was no built-up edge, and the chip was segmented in a manner not found in any other cuts (see Fig. 48). It was further concluded that a study of chip formation at very slow speeds can give no guidance as to what occurs under normal conditions; also, that a study of chip formation at the very commencement of cutting gives no indication of what occurs when cutting is continued long enough to become normal.

FIG. 48 EFFECT OF SPEED ON CHIP FORMATION IN MILD STEEL
(Speed of 7.45 ft. per min. After E. G. Herbert. Actual magnification 8.)

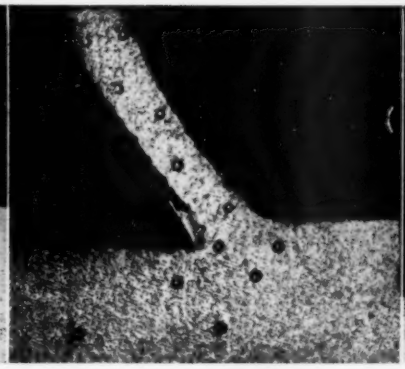

FIG. 49 EFFECT OF SPEED ON CHIP FORMATION IN MILD STEEL
(Speed of 61 ft. per min. After E. G. Herbert. Actual magnification 8.)

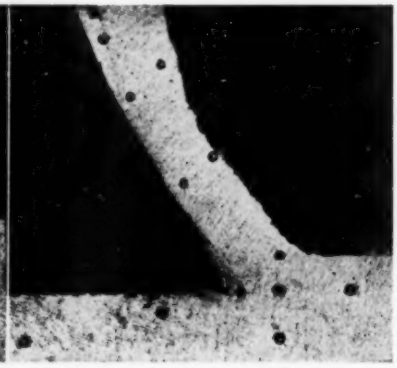

FIG. 50 EFFECT OF SPEED ON CHIP FORMATION IN MILD STEEL
(Speed of 165 ft. per min. After E. G. Herbert. Actual magnification 8.)

The speeds used in taking the cuts considered in this paper were all below the 18 ft. per min., considered by Herbert to be below the normal, and yet in several instances the conditions observed agree with Herbert's conclusions, as though higher speeds had been used. It seems, therefore, that possibly the conclusion of Herbert's as to the formation of chips at low speeds is not final. The present paper is considered as a first step in the investigation of "what happens when metal is cut." Photographs have been made of the tool only while stationary after taking a cut. It is hoped that this study may be continued into the second step of recording on a motion-picture film the continuous action of cutting on each of the materials at various speeds and from the starting of the cut until so-called normal conditions have been reached. Herbert's conclusions indicate that temperature must be an important factor in this so-called normal cutting—that is, cutting in which a built-up edge occurs. And yet, in this paper, the built-up edge was secured within 1/8-in. travel after the tool had started to cut at very low speeds. Many observations have been made in cutting at 20 ft. per min. on a planer, in which the beginning of 1/4 to 3/8 in. of the under side of the chip was burnished. From there on to the end of a 2- or 4-ft. length of cut, the under side of the chip was rough, presenting almost parallel cross-lines quite equally spaced. At the end of the cut the whole chip broke off and exposed a portion of metal which appeared to be the built-up edge. This held true for chips of 0.005 in. to 0.010 in. depth of cut. These cross-lines appear to be the pulled-out ends of the chip laminations. These ends appear as saw teeth or file teeth and actually point in a direction away from the tool point, while the bent under ends of the chip elements point toward the tool point. There seems to be no relation between the size of these file teeth and the chip elements, however. It does not seem from these teeth that the built-up edge is cast off frequently, as claimed by Herbert. There often is some evidence of the sloughing off of the built-up edge by the appearance of burnished spots or deposits at irregular intervals.

In the discussion of machinability Herbert reports that the measure of machinability is the hardness of the chip. The law of machinability takes into account not only all the characteristics of the metal, but also the machining process. Fig. 46(*b*) is a drawing of the photograph given in Fig. 46(*a*). The small dots are the places on which time-hardness values have been made with the 4-kg. Herbert pendulum hardness tester, equipped with a spherical-faced diamond of 0.5 mm. radius. The specimen was polished and etched after being cut from the original bar with a hand hacksaw. This represents the condition of the chip when the work was suddenly stopped during the process of continuous cutting. The specimen was mounted in pitch contained in a steel ring for polishing. It is seen that the hardness values of the uncut metal below the surface are smallest, averaging about 20. The hardness of the chip itself averages 50 per cent higher, while the hardness of the chip section in contact with the tool face averages 33 to 35. It is seen, therefore, that the hardness of the chip is greater than that of the uncut material, showing that it has been work-hardened. Herbert gives similar hardness tests results on chips of a wide variety of metals showing in every case that the hardness of the chip, which is the deformed material, is greater than that of the undeformed material. Manganese steel has a greater work-hardening capacity than most other steels, indicating one reason why it machines with difficulty. Brass and cast iron, on the other hand, have a very small work-hardening capacity, indicating their ease of machinability. The hardness of the chip depends on the capacity of the metal to become hard as a result of distortion and on the degree of distortion. Herbert explains that cast iron and brass are distorted very little. The author's observations, through the microscope, of continuous cutting do not bear this out. It was observed that leaded and non-leaded brass behaves, at the point of a cutting tool, as it is being formed into a chip, almost identically like steel; that the chip is made up of almost an infinite number of shear lines

or elements which may or may not be bound into segments shown in Figs. 14 to 25. Even Herbert's photomicrograph or a separate section of a brass chip shows that the structure of the chip itself is distinctly different from the original material, in that it has been sheared and compressed throughout.

Conclusions

It is not presumed that the study as outlined points the way to satisfactory and complete answers to De Leeuw's eleven questions listed at the beginning of the paper. The subject of "Chip Formation" and "What Happens When Metal Is Cut" has been considered and variously interpreted by many. It appears obvious that with variables such as materials, tool shapes, types of cutting, speeds, depths of cut, etc., complete correlation of the results of existing experimental observations is difficult. Many conflicting conclusions are reached regarding the various phases. Many conclusions are based on incomplete experiments or data. This study in the most part, for instance, is confined to deformation seen on the exterior of the metal. This study in itself is not final, but the first of two or three steps which, it is hoped, may make use of the X-ray and the moving picture. Final comprehensive conclusions can be drawn only after this information is complete.

Points which seem evident from the data presented as are follows:

1 It seems that the chips are divided into two types, those consisting of "sections" or groups of small laminations and those which are more or less "continuous," consisting entirely of uniform laminations.

2 Of those brass chips which are formed in sections, it appears that high lead (3 per cent), which is introduced into the metal as a free-cutting agent, causes laminations to be grouped into sections equal in size and of uniform shape at the beginning of the cut and at low speeds. For the low-leaded brass (1.44 per cent) under the same conditions, laminations were grouped into sections which were of unequal size and shape.

3 Comparing the chips of the high-leaded and low-leaded brasses when cut by a 15-deg. front-rake tool at 20 ft. per min., little difference appears. Both chips are "continuous," being made up uniformly of small elements and are not of the "section" type. The higher-leaded brass gives what appears to be a slightly more dense structure; that is, the individual laminations are smaller. Practically no difference exists in the horsepower required to remove a cubic inch per minute under similar conditions (*Trans. A.S.S.T.*, Vol. 16, No. 6, p. 659).

4 When high sulphur is used for free-cutting purposes such as in the screw-stock steel, it appears that the chip is more regular in its make-up as well as more dense in its structure. The individual laminations appear more distinct and regular than in the case of low-carbon steel.

5 In comparing chips of the screw-stock steel with those of the low-carbon steel when cutting with a 15-deg. front-rake tool at 20 ft. per min., the screw-stock-steel chips are seen to be more regular in their appearance and more continuous than those of low-carbon steel. The low-carbon-steel chip is badly deformed, very irregular, but obviously of the "flow" type—made up of laminated elements rather than grouped elements or "sections."

6 The chip of cast iron when removed at 20 ft. per min. appears also to consist of irregular laminations which easily become broken. The chip is very porous, and the laminations are held to one another apparently by mechanical contact only. The cast-iron chips appear to be very similar to, but less regular than, similar chips from cast Dow metal or cast manganese brass. The chips of both the latter when being cut at 20 ft. per min. by a 15-deg. front-rake tool are made up of loosely attached small laminations.

7 The size of the chips—that is, the ratio of the thickness of the chip to the original depth of cut—depends upon the kind of material cut, the tool shape or rake, the depth or cut, the speed of cutting, and whether cut wet or dry.

8 There appears to be some question as to the amount of metal in shear—that is, the slope of the lines of shear from the tool point to the surface of the metal as the front-rake angle of the tool is changed. It is definitely established that as the front-rake angle is increased, the cutting force expressed in pounds per square inch of original chip area is reduced in direct proportion for all metals (Ref. 21). This straight-line function, however, holds for some metals longer than others. For cast iron, when a front-rake angle of 25 to 30 deg. is reached, there appears to be no further reduction in force with increased rake angles. For carbon steel and most of the alloy steels, the straight-line function extends up to the 45-deg. front-rake angle. A satisfactory correlation between this straight-line function of reduced force with increased rake does not appear to be satisfactory when Figs. 37 to 42, inclusive, are considered, in which the low-carbon steel is cut with tools having front-rake angles of 15, 30, 45, and 60 deg., respectively. The angle of shear ahead of the tool point appears to be more nearly horizontal the smaller the front-rake angle. Figs. 38(*a*) and 42, in which the 30-deg. front-rake tool and the 60-deg. front-rake tool are cutting at a depth of 0.005 in., do not appear to bear this out, however.

9 It appears that when the tool starts to cut, the first few chips are of the "section" type (called "shear" type by Rosenhain). The material immediately ahead of the tool point bearing on the face of the tool seems to be crushed and pushed against the face of the tool by a resultant force which causes it to remain stationary in that position. This material then becomes the built-up edge which is forced into the material as the tool advances and seems to be the actual medium for separating the chip from the balance of the metal.

10 After the built-up edge is formed, the chips apparently become of the ribbon type (called "flow" type by Rosenhain), Many chips cut at high-speed are, however, of the "section" type.

11 Many photomicrographs by other experimenters show this built-up nose to consist of laminations. It is believed that these laminations are not the result of welding, but simply the result of compression under high pressure. Whether they actually consist of individual layers or simply material so distorted that it appears as layers seems uncertain. Rosenhain claims that the metal of the built-up edge, for brass, is continuous in itself and with the metal being cut. Herbert, on the other hand, claims that they are individual laminations gradually accumulated from the chip. It appears that this built-up edge is not material scraped from the cut surface by the tool edge, but rather material immediately ahead of the tool point which is crushed and pressed onto the tool face. It also appears that the cutting edge of the tool itself with depths of cut as low as 0.005 in. does not cut the surface or even drag over the surface left, but rather that the material ahead of the tool point is the only medium coming in direct contact with the cut surface left. Regardless of how fine the finish on a part, it does not appear as a burnished or clean-cut surface, but rather as a series of hills and valleys of the file-tooth type resulting from tear. For a good finish, these saw teeth become so small that they are not well observed by the eye.

12 It has been established that the force in pounds per square inch of original chip area required to remove the chip under given conditions becomes less as the original thickness of chip is increased (Ref. 21). Observations in this paper do not appear to be sufficient to make a correlation and complete

explanation possible. The material well ahead of the tool point is deformed even in addition to the so-called shearing of the metal into small laminations, and it is compressed and dragged below the cutting edge to a considerable proportion of the depth of cut. In addition, the chip is bent and compressed and forced over the face of the tool. Tearing in itself appears in most observations to be a small factor involved.

13 In cutting cast iron it is obvious that the cutting edge of the tool does a great portion of the work. After compressing the material ahead of the tool face and thereby forcing it over its face, the cutting edge proper scrapes along the finished surface, removing such irregularities as are left. These irregularities are then carried away with the balance of the chips.

14 When a lubricant is applied to the tool point, the steel chip appears to become more dense and more uniform in structure.

Acknowledgments

Grateful acknowledgment is made of the financial assistance secured for carrying on this project from the Department of Engineering Research of the University of Michigan. Prof. Claire Upthegrove of the Department of Chemical Engineering supervised the preparation of the photomicrographs shown in Figs. 43 to 45, inclusive, and also the analysis of these pictures. Mr. A. F. Parker, and Mr. H. A. Barnes did most of the preparing and setting-up of apparatus. All photographs were taken by them. The former proved very helpful in the preparation of the discussion.

Discussion

During the discussion of the paper the following questions were asked:

A. Slovak. Is not lack of homogeneity the reason for the varying shearing angles?

E. O. Waters. Is there any theory to account for the consolidation or grouping of the primary shear elements into definite and approximately equal sections?

K. W. Legg. What effect has the condition of the face of the cutting tool on the chip? Is it better that the tool be lapped or have ordinary ground surfaces?

R. V. Hutchinson. Can one push the ribbon off with a scraper, or do you have to regrind the tool to remove the chip or built-up edge? Have you made any determination of the cutting pressure normal to the surface of the main body of the work, with variations of rake from which some information could be had as to what goes on inside the chip?

H. L. Blood. Have you found that the cutting speed has a great effect upon the sticking of metal to the point of the tool?

George Bouvier. If the polish on the tool or the cutting lubricant used affects the type of chip formation, does not that indicate that there is no deposit of welded material?

Author's Closure

It appears that homogeneity in itself is not the reason for the varying shear angles. No metal is strictly homogeneous and yet its cutting action appears to be consistently alike at various points. Certainly, wide variations in uniformity of the metal will cause the formation of the chip at various points to be somewhat different. The chemical analysis and structure are thought to have greater influence on the formation of the chip and the shearing angles than lack of homogeneity itself.

The author knows of no theory to account for the consolidation of primary shear elements into definite and approximately equal sections. It appears that when this condition occurs some free-cutting agent such as lead or sulphur which has been introduced into the metal is the cause. Not enough information is available for the author to draw such definite conclusions, and certainly experimenters in general do not agree sufficiently well on this point to make such conclusions obvious.

Messrs. Legg and Bouvier have raised the question as to the influence on the formation of a chip of the condition of the face of the cutting tool. The tools used in these tests were very carefully ground and then lapped, so that they presented a somewhat smooth and polished surface and keen cutting edge. If this honed or lapped surface did exert any influence it seems that it would be in preventing the formation of a built-up edge on the tool or would assist in causing this built-up edge to slide off more frequently with the chip. This did not seem to be the case. It appears from practice that the value of lapping or honing the face of a cutting tool is questionable. In some

instances increased tool life has been observed, but in other cases no appreciable increase in tool life seemed to result. Undoubtedly, with extremely fine cutting of 0.001, 0.002, or 0.003 in., the keenness of the cutting edge resulting from honing or lapping becomes more apparent. The present paper, however, does not definitely answer this question. There may be less frictional resistance as the chip slides over the face of the tool after it has passed the built-up nose. The introduction of a cutting lubricant would probably accomplish the same thing as lapping. It does not seem to prevent the formation of the built-up nose, but does seem to give a finer and more uniformly broken-up structure of the chip. It does not seem safe to say that it prevents the building up of the built-up edge. It undoubtedly does prevent the welding of the material in the built-up nose even if welding occurs when cutting dry. Inasmuch as the built-up edge is formed both in dry and wet cutting, it would indicate then, that welding is not the process underlying the formation of the built-up nose.

Mr. Hutchinson's question is not altogether clear. When the built-up nose is retained on the tool face after the completion of a cut, it can be pushed off with a scraper or it may be ground off.

It is not a welded contact. Often by starting the tool with the built-up nose on its edge in a new cut, the first built-up nose is simply pushed off and a new one formed. The author has not made any determination of pressures cutting normally to the face of the main body of the work. All of his measurements have been parallel to the direction of cutting. These results for various rake angles may be seen in Trans. A.S.M.E., 1926, Vol. 48, p. 749.

In answering Mr. Blood's question as to the influence of speed upon the sticking of the metal to the point of the tool, it may be seen from the results given that the built-up nose was formed even though the cutting speeds were very, very low, so the author believes that the built-up edge is formed regardless of the speed of cutting.

Some Practical Deductions From the Theory of Lubrication of Short Cylindrical Bearings

By F. E. CARDULLO,[1] CINCINNATI, OHIO

In this paper the author tells of desirable characteristics which a fluid lubricant should have, and explains the effects of viscosity. He develops a theory with many mathematical equations on the phenomena of longitudinal flow of lubricants in bearings. Conclusions are given regarding general design and operation of bearings, the load carrying capacity, the power loss, and the ultimate rise in temperature of a bearing operating continuously with a particular eccentricity ratio.

A LUBRICANT is a substance interposed between two rubbing surfaces for the purpose of reducing friction or wear. Fluid lubricants must have the following characteristics: (1) They must have suitable viscosity at the temperature at which the bearing operates, (2) they must have the ability to wet the metals which form the rubbing surfaces and adhere to the rubbing surfaces under the conditions of service, (3) they must not attack the journal or the box chemically, and (4) they must not be acted upon by air or other substances with which they come in contact in such a manner as to change their lubricating qualities.

A suitable viscosity is always regarded as a primary requisite of a fluid lubricant, but a few oils, and many other liquids which have a suitable viscosity, are lacking in the other characteristics which are necessary. For instance, mercury has a suitable viscosity, and is also a good conductor of heat, which would be a valuable property in a lubricant, but it will not wet a steel or iron surface, and will attack most bronzes. Linseed oil and other drying oils are not satisfactory as lubricants because they absorb oxygen and become thick and gummy when exposed to the air.

If a drop of any liquid be placed upon a clean horizontal surface it will either form a spherical drop, the particles of the liquid clinging together so as to expose the minimum surface, or else it will spread into a thin film which wets the solid surface and spreads indefinitely. A fluid which gathers in drops is said to have a high surface tension while one which spreads and wets the surface is said to have a low surface tension.

Unless a solid is completely immersed in a liquid, a second fluid is always present. The surface tension of a liquid depends upon the nature of the second fluid present, as well as of the solid surface with which it is in contact. Ordinarily the second fluid is air. It may, however, be some other gas, or a vapor or liquid. In a steam-engine cylinder, iron, oil, steam, and water are all in contact. At the high temperatures encountered in such service, a pure mineral cylinder oil will not wet the iron, since its surface tension is greater than that of very hot water in the presence of steam. The hot water therefore wets the iron, while the cylinder oil gathers in drops and becomes ineffective as a lubricant. The addition of a small percentage of tallow to the mineral oil will lower its surface tension below that of the water, so that the "blended" oil, as it is called, will wet the iron of the cylinder under the conditions of service.

It has been found that the addition of small quantities of free fatty acids to a mineral lubricating oil lowers its surface tension in the presence of metal, or in other words improves its ability to spread on a metallic surface and to wet it. Under certain conditions particularly in the presence of moisture, free acids in a lubricant will attack the bronze or the steel, roughening the surface and injuring the bearing. We are therefore limited to the use of those organic acids which are least active in attacking metals, and they must be used in such minute quantities as to have no objectionable effects.

Certain types of oils such as the drying oils already mentioned which by the absorption of oxygen from the air, or by other chemical change, gum or thicken, or oils which evaporate, carbonize, or become corrosive, rancid, or thin when exposed to moderate heat, to humidity, or to air, cannot be used for lubricants, although they have many of the properties necessary in a lubricant. This class includes all drying oils, mineral oils containing certain sulphur compounds, and all oils which are adversely affected by heat.

Of the four properties mentioned as necessary to a fluid lubricant, the one most readily susceptible of measurement is viscosity, and this property has received the most attention from investigators. Viscosity is sometimes called "body" or "thickness," and oil of high viscosity is said to be "heavy" even if it is of low specific gravity, and similarly a "light" oil is one of low viscosity even though it may sometimes have a dark color and a high specific gravity. In general high viscosity or "heavy" commercial oils used as lubricants have a dark color and a high gravity, while "light" oils or oils of low viscosity are usually also light in color and of low specific gravity. This is not, however, invariably the case.

Viscosity may be defined as resistance to flow. Experimental investigation shows that this resistance is in the nature of a resistance to a shearing movement and is proportional to the rate of shearing. It is different in its nature from the resistance to flow due to eddying and to other inertia effects. Resistance due to inertia is proportional to the square of the velocity of flow, while resistance due to viscosity is proportional to the first power of the velocity. Viscosity effects are predominant in the case of small quantities, thin films, low velocities, and of thick fluids. Inertia effects are predominant in the case of thin fluids, especially those of high specific gravity, fluids flowing in large masses, and fluids flowing at high velocities. Inertia effects are negligible in the case of bearing phenomena.

---

[1] Chief Engineer, G. A. Gray Co. Mr. Cardullo was educated in the public schools of Titusville, Pa., and at Cornell University, where he received the degree of M.E. in 1901. Until 1905 he was engaged in commercial work in the design of heavy gas engines and steam-pumping engines. From 1905 to 1908 he was an instructor and assistant professor of mechanical engineering subjects at Syracuse University, and from 1908 to 1914 was professor of mechanical engineering at New Hampshire College. The following year he became chief draftsman of the Pierce Arrow Motor Car Company, leaving to become engineer of tests with the Curtiss Aeroplane and Motor Corporation. Since the war Mr. Cardullo has been associated with the G. A. Gray Co. at Cincinnati, Ohio, as chief engineer.

Presented at the National Meeting of the Machine Shop Practice Division, Cincinnati, Ohio, September 24 to 27, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

To explain the effects of viscosity consider a cube of liquid as shown in Fig. 1. The face *ABCD* is moved in the direction of the arrow with a constant velocity, while face *EFGH* is fixed in position. The liquid will be sheared along every plane parallel with and lying between *ABCD* and *EFGH*, and the internal forces of the liquid will resist this shearing action.

Experiments show that with any given fluid the force required to move the face *ABCD* is directly proportional to the velocity, directly proportional to the area sheared, and inversely proportional to the thickness *AE*. It also varies with the temperature, usually being less as the temperature rises. The force in pounds required to shear an inch cube of a liquid at the rate of 1 in. per sec. is known as the absolute or dynamic viscosity of the liquid in the inch-pounds-second system. Scientists usually give the absolute viscosity of a liquid in C.G.S. units, or in dynes required to shear a centimeter cube at the rate of one centimeter per second under standard conditions.

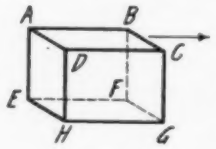

FIG. 1

The absolute viscosity, in either the C.G.S. system or the inch-pounds-second system, of a fluid suitable for use as a lubricant, is so small that it is not a practical unit of measurement. Accordingly the viscosity of a lubricant is usually expressed by the number of seconds required for a standard quantity of the lubricant to flow through a small tube of specified bore and length under standard conditions of head and temperature. Such a viscosity is nearly proportional to the absolute viscosity of the fluid.

Referring again to Fig. 1, let *EFGH* be a fixed plate having an area of S square inches, and *ABCD* a plate of equal area parallel to the first, and moving in its own plane with a velocity of V in. per sec. The thickness T of the film of fluid lying between the two plates is of course the distance *AE*. Then the force in pounds required to maintain the movement of plate *ABCD* at a velocity of V inches per second is:

$$F = \frac{KSV}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The constant K is the absolute viscosity of the fluid and is

$$K = \frac{FT}{SV} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

It follows from Equation [2] that the physical dimensions of absolute viscosity are pound-seconds per square inch, or in C.G.S. units dyne-seconds per square centimeter.

Putting this equation into plain language, the following facts are obtained regarding the friction of fluid lubricated surfaces: (1) All other things being equal, the greater the area of the rubbing surfaces the greater the friction; (2) all other things being equal, the thinner the film of lubricant the greater the friction and consequently the higher the temperature at which the bearing will run; (3) all other things being equal, the higher the velocity of rubbing the greater will be the friction and the higher the temperature at which the bearing will run; and (4) all other things being equal, the more viscous the lubricant the greater the friction and the higher the temperature at which the bearing will run.

In any actual bearing, the area of the rubbing surface, the thickness of the film of lubricant, the velocity of rubbing, the viscosity of the lubricant, and the temperature of the bearing are not independent factors. The area of bearing surface, the viscosity of the lubricant, the load, and the velocity of rubbing all affect the film thickness, while the temperature of the bearing affects the viscosity of the lubricant. The problem becomes too complex for simple statement, or even for elaborate mathematical analysis, and must be solved by semi-empirical methods.

In order to understand more clearly what occurs in a copiously lubricated bearing, an endeavor will be made to develop an approximate physico-mathematical theory for a plain cylindrical bearing. Except for very short bearings this theory is a first approximation only, and its principal value lies in the fact that it serves to explain what occurs in a bearing under conditions of service. From this theory it may be learned how best to supply the lubricant, the best forms for oil grooves, where the wear will occur on the surface of the box, why suitable clearance is necessary in a bearing, and what the general effect will be if the load, the speed, the clearance, the viscosity of the lubricant, the length of the journal, or any other feature of design or operation be changed.

Fig. 2 shows a section in a plane of revolution of a cylindrical journal of radius r revolving in a cylindrical box of radius $r + c$,

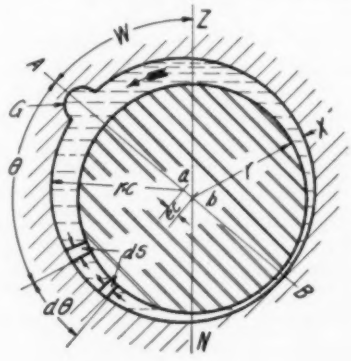

FIG. 2

where c is one-half the allowance for a running fit. This quantity c (or sometimes the allowance $2c$) is called the running clearance. The actual clearance, or the distance from a point on the surface of the journal to the nearest point on the surface of the box, is a very variable quality and it should not be thought of as being fixed when the box is machined.

Point a is the trace of the axis of the box and point b is the trace of the axis of the journal. The journal and box are not concentric, their centers being separated by the distance from a to b. This distance is designated by the symbol ec, where e is a proper fraction which is called the eccentricity ratio of the bearing. A variable quantity x is the distance at any point of the surface of the journal from the nearest point on the surface of the box, and is the film thickness of the lubricant at that point.

Assume that the weight of the journal and its load acts vertically along the line ZN, while line AB, making angle W with ZN, passes through the centers a and b. Assume a groove G, at the point where the film thickness is a maximum, to be continually filled with oil which wets both the journal and the box. As the journal revolves in the direction of the arrow, the oil tends to travel with the journal, and also to remain stationary with the box. The relative motion continually shears the oil, the velocity of any particular point in the oil film depending upon its relative distance from the surface of the moving journal and the stationary box. At the groove G, and also at the ends of the box, the average circumferential velocity of the oil will be one-half that of the journal. At all other points the variation in the static pressure of the lubricant (which is developed by the pumping action produced by the motion of the journal) tends to oppose or accelerate the rotation of the film of lubricant, so that its actual average circumferential velocity is less

than one-half the speed of the journal, and varies from point to point in a manner governed by mathematical relations so complicated that the general solution of the problem has hitherto defied analysis.

In order to simplify the theory let it be assumed that the velocity in the plane of rotation of any point in the film is proportional to its distance from the surface of the box, and that at the surface of the journal it is equal to the velocity of the journal. Hence the average velocity of rotation of the film is one-half that of the journal.

Consider an element or filament of the lubricant, distant angle Θ from line AB. Its thickness in a radial direction will be

$$x = c\ (1 + e \cos\Theta) \quad \ldots\ldots [3]$$

After this filament is moved the further angular distance $d\Theta$, the change in thickness will be

$$dx = -ec \sin\Theta\, d\Theta \quad \ldots\ldots [4]$$

If the length of the journal be L and the width of the filament be ds in each case, the change in volume will be

$$dU = Ldxds = -Ldsce \sin\Theta\, d\Theta \quad \ldots\ldots [5]$$

the minus sign indicating that the volume diminishes as Θ increases. The quantity of lubricant represented by this change in volume is squeezed out at the ends of the box, one-half being squeezed out at either end.

It will now be seen that in the case of such a bearing the revolving journal continually carries into the clearance space from the distributing groove G a sheet of oil whose mean speed is assumed to be one-half that of the journal. Since the space into which this oil is carried becomes steadily thinner, the sheet of oil is compelled to spread out at right angles to the direction of journal rotation, and the most of it is squeezed out at the ends of the box, between the groove G and the point of minimum film thickness. This action results in an axial component of flow. Sommerfeld, following the work of Reynolds, has developed a theory of lubrication of cylindrical bearings which ignores the axial flow, which is of course the theory of a bearing of infinite length. According to Sommerfeld's theory the mean circumferential velocity of the film at any element Θ_1 is to one-half the speed of the journal as the thickness of the film at the element where the maximum pressure occurs is to the thickness of the film at element Θ_1. According to Sommerfeld's theory the pressure of the lubricant is constant along the whole length of any element, being the same at the ends as at the center. It would follow from this that the allowable load is strictly proportional to the length of the bearing, and that circumferential grooves in the box have no adverse effect. Such is not the case, and Sommerfeld's theory leads to erroneous conclusions regarding the effect of oil grooves and the allowable loads on short bearings. Sommerfeld's theory, however, is of value in giving the limiting pressure which can occur at the center of any element of a long bearing.

In flowing endwise through the clearance space a back pressure is set up which varies from point to point over the surface of the box. This fluid pressure supports the journal so that it floats on a moving film of oil. The effect of the rotation of the journal is to produce a pumping action which maintains the fluid pressure that supports the shaft.

To investigate the axial component of the velocity of flow, and the amount of pressure which may be set up by this action, if $2w$ is assumed to be the angular velocity of the journal, then w will be the angular velocity in radians per second of the lubricant. The time required for the filament of lubricant which has already been considered to move the angular distance $d\Theta$ will then be $\frac{d\Theta}{w}$. Dividing the change in volume by twice the area of the filament multiplied by the time, the mean value of the axial component of the velocity with which the oil flows from the end of the journal at any point will be obtained. Solving the following equation results:

$$\frac{dU}{2\,xds\,\dfrac{d\Theta}{w}} = \frac{-Ldsce \sin\Theta\, d\Theta\, w}{2\ c\ (1 + e\cos\Theta)\ ds\ d\Theta} \quad \ldots\ldots [6]$$

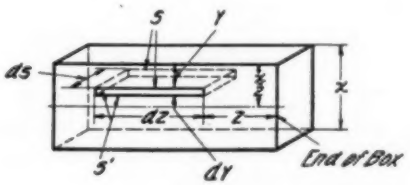

FIG. 3

Clearing this the following is obtained for the mean axial velocity of the lubricant at any point at the ends of the box:

$$\overline{V} = \frac{L}{2}\, w\, \frac{e \sin\Theta}{1 + e \cos\Theta} \quad \ldots\ldots [7]$$

We will now investigate the effect of this axial flow of lubricant in producing a hydrostatic pressure sufficient to lift the shaft. In Fig. 3 is shown an axial section greatly enlarged, through the filament of lubricant already considered. The filament is flowing endwise from the center section of the box and the portion considered is flowing to the right and lies to the right hand of the center of the box. Out of this filament a very small portion bounded by transverse planes and surfaces S and S' is taken. The length of the portion in an axial direction is dz, the width in a circumferential direction (i.e., perpendicular to the plane of a paper) is ds, as before, and the thickness in a radial direction is dy, the distance between surfaces S and S'. The difference in pressure in pounds per square inch at the two ends of the portion is dP.

Since the thickness of the filament is x, and the distance from the surface of the journal to the surface S of the element is y, the distance from the center of the filament to the surface S of the element is $\left(\frac{x}{2} - y\right)$. At the center of the filament the axial velocity is a maximum, dropping off to zero at the surface of the box or the journal. The axial shearing force at the center of the filament parallel to S is zero. At S the shearing force in pounds per square inch is

$$\frac{F}{A} = \frac{d\,Pds\left(\frac{x}{2} - y\right)}{dsdz} = \left(\frac{x}{2} - y\right)\frac{dP}{dz} \quad \ldots\ldots [8]$$

From Equation [1] the shearing stress in pounds per square inch is

$$\frac{F}{A} = \frac{KV}{T} \quad \ldots\ldots [9]$$

Substituting for T the value dy, and for V the value dv, which is the difference in velocity between the surfaces S and S'

$$\frac{F}{A} = \frac{KdV}{dy} = \left(\frac{x}{2} - y\right)\frac{dP}{dz} \quad \ldots\ldots [10]$$

Transposing [10]

$$K\,dV = \frac{dP}{dz}\left(\frac{x}{2} - y\right)dy \quad \ldots\ldots\ldots\ldots\ldots [11]$$

Integrating [11] between the corresponding limits of V = zero when y = zero and $V = V$ when $y = y$

$$KV = \frac{dP}{dz}\left(\frac{xy}{2} - \frac{y^2}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots [12]$$

Solving for V, the axial velocity is obtained at any point distant y from the box or the journal.

$$V = \frac{1}{K}\frac{dP}{dz}\left(\frac{xy}{2} - \frac{y^2}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots [13]$$

In order to obtain the mean velocity from the center of the filament to the surface of the box or journal, i.e., from y = zero to $y = x$ we may write

$$\overline{V} = \int_0^{\frac{x}{2}} \frac{V dy}{\frac{x}{2}} = \frac{2}{x}\int_0^{\frac{x}{2}} V dy \quad \ldots\ldots\ldots\ldots [14]$$

Substituting [13] in [14]

$$\overline{V} = \frac{2}{x}\int_0^{\frac{x}{2}} \frac{dP}{Kdz}\left(\frac{xy}{2} - \frac{y^2}{2}\right)dy \quad \ldots\ldots\ldots\ldots [15]$$

By transposing this becomes

$$\overline{V} = \frac{dP}{Kxdz}\int_0^{\frac{x}{2}} (xydy - y^2dy) \quad \ldots\ldots\ldots\ldots [16]$$

Integrating

$$\overline{V} = \frac{dP}{Kxdz}\left[\frac{xy^2}{2} - \frac{y^3}{3}\right]_0^{\frac{x}{2}} \quad \ldots\ldots\ldots\ldots [17]$$

Substituting the limiting values this becomes

$$\overline{V} = \frac{dPx^2}{12\ Kdz} = \frac{x^2}{12\ K} \times \frac{dP}{dz} \quad \ldots\ldots\ldots\ldots [18]$$

Equation [7] gives the mean axial velocity of the filament of the lubricant at a point distant $\frac{L}{2}$ inches from the center of the box. At a point z inches from the edge of the box the quantity $\frac{L}{2} - z$ may be substituted for the quantity $\frac{L}{2}$ and the following equation results

$$\overline{V} = \left(\frac{L}{2} - z\right)\frac{we\,\sin\Theta}{1 + e\,\cos\Theta} \quad \ldots\ldots\ldots\ldots [19]$$

which gives the mean axial velocity of the lubricant at any point on the surface of the box, between the elements of maximum and minimum clearance. Equating [18] to [19] and substituting the quantity $c(1 + e\,\cos\Theta)$ for x, we have

$$dP\,\frac{c^2(1 + e\,\cos\Theta)^2}{12\ K} = wce\,\sin\Theta\left(\frac{L}{2} - z\right)dz \ldots [20]$$

Integrating both sides of this equation between the corresponding limits of P = zero and $P = P$ and $z = 0$ and $z = z$,

$$P\,\frac{c^2(1 + e\,\cos\Theta)^2}{12\ K} = wce\,\sin\Theta\left(\frac{Lz - z^2}{2}\right) \ldots [21]$$

Solving this equation for P

$$P = 6K\,\frac{w}{c^2}\,\frac{e\,\sin\Theta}{(1 + e\,\cos\Theta)^2}\,(Lz - z^2) \quad \ldots\ldots [22]$$

This equation gives the value of the hydrostatic pressure P of the lubricant at any point distant angle Θ from the element of maximum clearance, and distant z inches from the nearest end of the box, the values of L, e, K, w, Θ, and c being as previously given.

It is now in order to determine the effect of changes in length of the bearing on the amount and distribution of this hydrostatic pressure. In order to do this then may be substituted for z in Equation [22] the quantity bL, where b is a factor which may have any value between zero and one-half, being zero at the end of the bearing and one-half at the center. This gives

$$P = 6K\,\frac{w}{c^2}\,\frac{e\,\sin\Theta}{(1 + e\,\cos\Theta)^2}\,L^2\,(b - b^2) \quad \ldots\ldots [23]$$

If now there is a series of bearings of different lengths (i.e., with different values of L), points having the same values for Θ and b, that is located at the same angular distance from the A-B axis and the same proportion of the length from the center of the bearing, will be homologous points. If one series of homologous points are taken, the function b is the same for each of the bearings and the factor $(b - b^2)$ may be represented by B. Substituting B in equation [23] and combining the constants,

$$P = K'BL^2\,w\,\frac{e\,\sin\Theta}{c^2\,(1 + e\,\cos\Theta)^2} \quad \ldots\ldots\ldots [24]$$

An inspection of this equation shows that at homologous points in two or more short bearings, when the other variables are equal, the hydrostatic pressure is proportional to the square of the length of the bearing.

The load-carrying capacity of a bearing is equal to the integral of the vertical components of the hydrostatic pressures acting on all of the several areas of the bearing. Since these pressures for different bearings are proportional to the squares of the lengths, and since the areas of the bearings are proportional to the lengths, it follows that the load-carrying capacity of a bearing is proportional to the cube of the length, when the diameter, speed, eccentricity ratio, and running clearance of the bearing are fixed.

An inspection of Equation [24] shows that for any given eccentricity ratio, the curve of pressure distribution for different angles in any particular plane perpendicular to the axis of a bearing is of the same form, whatever the viscosity of the lubricant, the length of the bearing, the point along the length chosen, the speed of the journal, and the operating clearance of the bearings. The form is, however, a function of the eccentricity ratio of the bearing. This follows from the fact that Equation [23] may be divided into two factors, one of which is

$$\frac{6\,K\,(b - b^2)\,L^2}{c^2}$$

while the other is

$$\frac{e\,\sin\Theta}{(1 + e\,\cos\Theta)^2}$$

The first factor is independent of the angular position of the point considered while the second factor is a somewhat complicated function of the eccentricity ratio and of the angular position of the point considered. So long as the eccentricity ratio of the bearing remains constant, the pressure at any particular

point in the bearing depends on its distance from the end of the bearing, and is proportional to the operating viscosity of the lubricant and the speed of rotation of the journal, and inversely proportional to the square of the operating clearance.

From Equation [24] Table 1 has been computed. In this the quantity P is proportional to the pressure at a series of points in any given plane of rotation of the bearing, and is computed for different values of the eccentricity ratio ranging from $e = 0.4$ to $e = 0.9$, using the formula

$$P = \frac{100\ e \sin \Theta}{(1 + e \cos \Theta)^3} \qquad [25]$$

The value of $P \sin \Theta$ and $P \cos \Theta$ for different values of e and Θ are then computed, and by means of Simpson's rule, the mean value of the components of P perpendicular to and parallel to the AB axis are computed for each value of e. The load itself, which is proportional to the resultant of these components, is taken as the square root of the sum of the squares of the two mean components so found. Since the direction of the load is in the ZN axis, by dividing the component perpendicular to the AB axis by the resultant of both components, the sine of W is obtained.

In Table 2, column 1 are given different values of the eccentricity ratio, in column 2 the corresponding components of the load perpendicular to the AB axis, in column 3 the components of the load parallel with the AB axis, in column 4 angle W, and in column 5 the resultants of the perpendicular and parallel components, or the loads on the bearing. As the load increases from 30 to 1570, the value of e increases from 0.4 to 0.9. When the load is small the point of maximum clearance is about 60 deg. from the vertical in the direction of rotation and the point of minimum clearance about 60 deg. from the bottom of the box. As the load increases the angle W diminishes so that at the highest load computed, when $e = 0.9$, the point of minimum clearance is only 20 deg. from the bottom of the box.

In order to illustrate the angular distribution of pressure in accordance with this theory, values of P for different values of Θ have been plotted from Table 1 in Fig. 4. P is represented by the radial distance from the circle which represents the journal, to the outer line which represents the limit of P. It has been plotted for values of the eccentricity ratio of $e = 0.6$, $e = 0.7$, $e = 0.8$, and $e = 0.9$. In the first three cases the length of the scale line represents 500 units pressure. In the last case, however, the same length of line represents 2000 units pressure, so that the radial scale for $e = 0.9$ is only one-quarter as great as it is for the other three cases. In Fig. 5 is shown graphically the relation between the eccentricity ratio and the load, as plotted from Table 2.

0.9	514.0	1432.0	19	5	1570.0

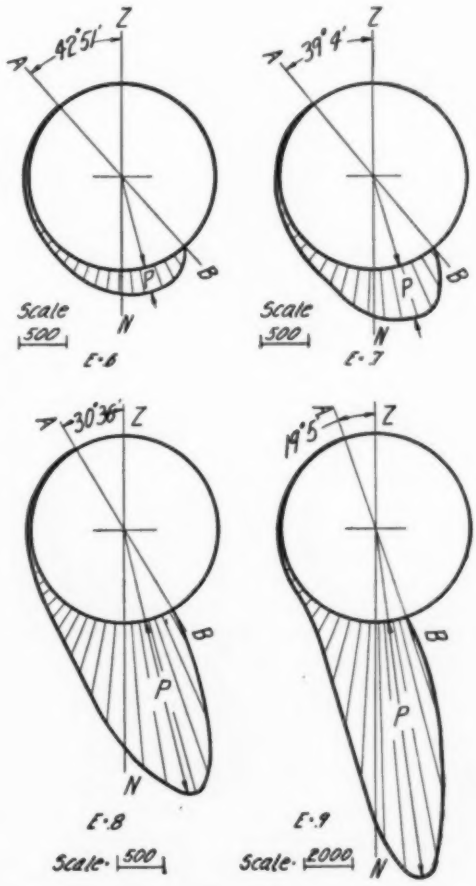

FIG. 4

These curves show graphically a number of things, among them that the pressure increases very rapidly for high values of the eccentricity ratio, that for high values of the eccentricity ratio the pressure is concentrated along a small portion of the surface at the bottom of the box, and that the effect of the pressure over the greater portion of the left-hand side of the box is only to prevent the journal from moving to the left and therefore to maintain the angle W at its proper value.

The curves in Fig. 4 show that with high values of the eccentricity ratio the maximum pressure occurring in a bearing may be many times greater than the mean pressure obtained by dividing the load by the product of the length and the diameter. Under such conditions the localized pressure may become so great as to cause the material of the box to flow, particularly if the box be formed of some plastic material like babbitt. This will result in a readjustment of the pressure distribution in such a manner as to give lower localized pressures. The box, however, will no longer be truly cylindrical and the mathematical

portion of the theory will no longer be tenable. Probably one of the advantages of a bearing metal having a low compression yield point is the fact that under the conditions of service it adjusts itself in such a manner as to give a more equal pressure distribution and a greater minimum film thickness.

It may be pointed out that from the point where the intensity of pressure is a maximum to the point of minimum clearance (point B), where the pressure becomes zero, the change in pressure tends to assist instead of oppose the rotation of the film of lubricant. At point B the lubricant flows past the surface of the box at a speed greater than one-half the speed of rotation of the shaft. This phenomenon, which is ignored in this mathematical theory, is analogous to one already noted, namely, that the lubricant rotates at less than one-half the speed of the shaft in the region where the pressure is increasing rapidly with increasing values of Θ. The effect of this phenomenon is to reduce angle W and to concentrate the pressure just in front of the region of minimum clearance.

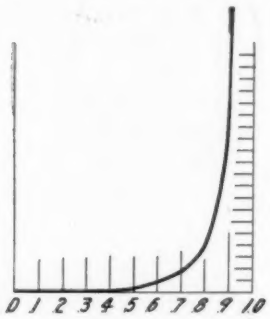

FIG. 5

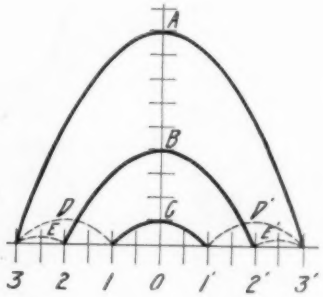

FIG. 6

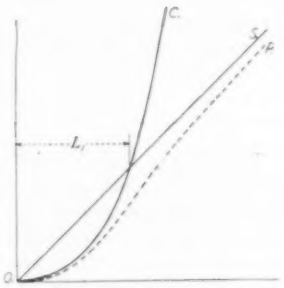

FIG. 7

In Fig. 6 is shown the relation between the pressure and distance measured along the axis of bearings 2 in., 4 in., and 6 in. long. It will be seen from these curves that the load-carrying capacity, which is proportional to the area under the curve, increases very rapidly with the length, in the case of a short bearing. It will be interesting to compare the relation between length and load-carrying capacity shown by the theory of short bearings and that shown by Sommerfeld's theory.

Referring to Fig. 7, horizontal distances represent bearing lengths, while vertical distances represent load-carrying capacities. The line OS, which is a straight line passing through the origin, represents the relation between the load-carrying capacity and the length of the bearing according to Sommerfeld's theory. Line OC, which is a cubical parabola, represents the relation between the length and the load-carrying capacity of a bearing in accordance with the theory of short bearings. It will be noted that the two lines cross at the point where the length is L_1. For lengths less than L_1 the theory of short bearings gives lower values for the load-carrying capacity, while for lengths greater than L_1, Sommerfeld's theory gives lower values for the load-carrying capacity. The actual load-carrying capacities of bearings are less than the values given by ordinates to the line OC for bearings shorter than L_1, and less than the values given by ordinates to the line OS for bearings longer than L_1, because of the combined effects of end leakage (which is neglected by Sommerfeld's theory) and the effect of the pressure differential in restraining the circumferential flow (which is neglected in the theory of short bearings). Consequently the true load-carrying capacities of bearings will follow some such line as the dotted line OP, which is tangent to line OC at the origin, is asymptotic to line OS, and lies entirely below both of them.

According to some computations made by Prof. E. O. Waters the length L_1 will lie somewhere between 1 and $1^1/_2$ times the diameter of the shaft.

In this connection it may be pointed out that a circumferential groove in the surface of the bearing has the same effect as though the bearing were divided by the groove into two parts. For instance, in Fig. 6 a bearing having the relative length of 6 has a load-carrying capacity proportional to the area included under the curve 3A3. If two circumferential grooves are cut at points 2 and 2′, distant 1 from each end, the load-carrying capacity of the bearing will be reduced to the area included under the three curves 3E2′, 2B2′, and 2′E′3′. In the same way if these grooves are moved to the points 1 and 1′, the load-carrying capacity will be still further reduced to that included under the three curves 3D1, 1C1′, and 1′D′3′.

In order to conserve the lubricant it is desirable to cut circumferential grooves near the ends of the bearing. These grooves catch the oil which flows out at the ends and return it to the groove G. These grooves should, however, be cut close to the edge of the bearing so that the effective length of the bearing will be a maximum.

An inspection of Table 2 and Fig. 5 shows a very interesting relation between the load on the bearing, which is designated by the symbol F, and the eccentricity ratio. This may be expressed very closely by the equation

$$F = 14.86 \frac{e^{0.3711}}{(1-e)^{2.041}} \quad \ldots\ldots\ldots\ldots\ldots [26]$$

or approximately, by the equation

$$F = K \frac{e^{0.4}}{(1-e)^2} \quad \ldots\ldots\ldots\ldots\ldots [27]$$

The factor K depends upon the units employed, the dimensions of the bearing, the speed of the journal, and the viscosity of the lubricant. The figure 14.86 is merely the particular factor which fits the conditions which form the basis of Table 2. For the purpose of computation this equation may be written in the form

$$\log F = 1.1719 + 0.3711 \log e - 2.041 \log (1-e) \ldots [28]$$

Another interesting relation is that between the running clearance and the value of e for a given value of the load. For a given eccentricity ratio the load will be inversely proportional to the square of the running clearance. An equation of the following form may, therefore, be written:

$$F = K \frac{e^{0.4}}{c^2(1-e)^2} \quad \ldots\ldots\ldots\ldots\ldots [29]$$

In this equation the function c (1-e) is the minimum film thickness. Solving for the minimum film thickness, an expression is obtained of the form

$$c(1-e) = K\frac{e^{0.2}}{\sqrt{F}} \quad [30]$$

It is probable that in usual bearings the value of e ranges from 0.7 to 0.9. Consequently, the fifth root of e will range from 0.932 to 0.979, a range of only about 5 per cent.

It is apparent from Equation [30] that the value of the minimum film thickness is practically independent of the value of c, the running clearance, and varies inversely with the square root of the load.

It is probable that a bearing fails when the minimum film thickness becomes too small. If such is the case, the value of the minimum film thickness under operating conditions is the most important factor determining the load-carrying capacity of a bearing. The minimum film thickness and therefore the load-carrying capacity are sensibly independent of the running clearance and it follows that the running clearance may theoretically have any reasonable value greater than about three times the allowable minimum film thickness. However, there is an operating clearance which will give the most satisfactory condition for a given speed and diameter of bearing. In general, longer bearings should have larger operating clearance than short bearings, and within reasonable limits the effect of too much or too little clearance may be counteracted by using a lubricant of high or low viscosity.

Small values for the running clearance give a bearing which is inclined to run hot and in which small changes of temperature will produce considerable changes in the running clearance. Moreover, if small running clearances are adopted, very small tolerances are necessary in order to avoid tight bearings. For many reasons it is desirable that the running clearance should not be reduced to the minimum at which the bearing will operate satisfactorily, under perfect conditions.

From the theoretical standpoint there is no reason why the running clearance should not be quite large. There are, however, many practical objections to a "loose" bearing. A loose bearing will necessarily have a high value for the eccentricity ratio, and hence the oil pressure will be concentrated along a narrow zone near the bottom of the box. When there are variations in the speed or in the direction of the load, a loose bearing will give more or less trouble.

For bearings of the usual speeds and diameters the minimum value of the allowance for a running fit may be taken as

$$2c = 0.0001\sqrt{D \times \text{r.p.m.}} \quad [31]$$

in which D is the diameter of the journal in inches, $2c$ is the minimum allowance for running clearance, and r.p.m. is the speed of the journal in revolutions per minute. The maximum allowance for good work is about twice this amount.

For speeds of less than 100 r.p.m. the allowance should be

$$2c > 0.001\sqrt{D} \quad [32]$$

The above allowances are the result of practical experience, but are in general in accordance with the theory as developed.

Certain general considerations regarding the design and operation of bearings can be deduced by means of the theory developed. If it is assumed, as seems reasonable, that the minimum film thickness is the most important of the factors which determine whether or not a bearing will operate successfully, conclusions embodied in the following rules are arrived at.

1 The load-carrying capacity of a bearing is proportional to its diameter.

2 The load-carrying capacity is proportional to the operating viscosity of the lubricant, i.e., to the viscosity of the lubricant at the temperature which the lubricating film attains in operation.

3 The load-carrying capacity is proportional to the speed of rotation in revolutions per minute.

4 The load-carrying capacity of a bearing is proportional to the surface speed of the journal, since this is proportional to the product of the diameter and the speed in revolutions per minute.

5 The load-carrying capacity of a bearing is a function of its length. For very short bearings such as eccentric straps, the theory developed in this paper is substantially correct, and it is proportional to the cube of the length. For very long bearings Sommerfeld's theory is substantially correct and it is proportional to the length. For bearings of the usual proportions, the load-carrying capacity is a function of the length approximately proportional to some power of the length greater than the first and less than the third. The load-carrying capacity of a bearing may possibly be represented by an empirical equation of some such form as

$$F = KL^{\left(\frac{3}{aL+1}\right)} \quad [33]$$

in which a is a constant.

The power loss in a bearing depends upon the eccentricity ratio. With the same operating clearance, operating viscosity, and speed, a bearing with a high eccentricity ratio will have a greater power loss than one with a low eccentricity ratio. If it is assumed that the eccentricity ratio remains constant, the following general rules are obtained.

6 The power loss in a bearing is proportional to the square of the diameter.

7 The power loss in a bearing is proportional to the length.

8 The power loss in a bearing is proportional to the square of the speed in revolutions per minute.

9 The power loss in a bearing is proportional to the square of the surface speed of the journal.

10 The power loss in a bearing is inversely proportional to the operating clearance.

11 The power loss in a bearing is proportional to the operating viscosity of the lubricant.

The preceding rules lead directly to the following conclusions regarding the ultimate rise in temperature of a bearing operating continuously with a given eccentricity ratio.

12 The rise in temperature of a bearing is independent of its length.

13 The rise in temperature of a bearing is proportional to its diameter.

14 The rise in temperature of a bearing is proportional to the operating viscosity of the lubricant.

15 The rise in temperature of a bearing is proportional to the square of the number of revolutions per minute.

16 The rise in temperature of a bearing is inversely proportional to the running clearance.

The 16 rules for the general behavior of a bearing which have been given assume that all the factors except the one considered remain constant. However, two or more factors usually vary at the same time, and any factor which varies affects in some degree the eccentricity ratio of the bearing. These rules are therefore not to be taken as a numerical expression of the behavior of a bearing, but rather as a guide to the general effect of variations in these factors. For instance a high-speed bearing usually has a larger running clearance than a low-speed bearing, so that although the increased speed tends to increase the power loss and the operating temperature, the increased

running clearance tends to produce an opposite effect. In considering the effects of diameter it must be remembered that bearings of large diameter have correspondingly large running clearance, and the rules regarding the effect of diameter and running clearance on power loss and operating temperature should be read in the light of this fact.

The 16 rules, the theory developed in this paper, and in a still larger measure, Sommerfeld's theory, also assume certain conditions which are never realized in practice, namely, that the box and the journal are both truly round and perfectly smooth, that they are rigid and maintain their shape, and that their axes are parallel and not affected by deflections produced by the load. On account of the effect of deflection an increase in the diameter of the bearing will be of greater practical value in increasing the load-carrying capacity than the rules indicate, while an increase in the length of the bearing will be of less value than the rules indicate. Because of imperfections in roundness and uniformity small operating clearances are less satisfactory than the rules would indicate.

The phenomena which occur in the operation of a bearing are so complex, and the several variables are so interrelated, that only the most general conclusions can be drawn concerning the behavior of bearings from such a mathematical theory as has been developed. When to these considerations is added the fact that practical bearings depart from their theoretical form both because of imperfections of manufacture and lack of perfect rigidity in the parts, it is found that their behavior is apt to be somewhat erratic, and the rules derived are indicative merely of the general trend of their behavior.

Discussion

MAYO D. HERSEY.[2] Many of the sixteen conclusions offered in this paper are not new and can be derived by elementary methods without the aid of the mathematical equations developed herein. This criticism applies especially to the conclusions regarding power loss, since the author has not ventured to outline any method for calculating the frictional resistance of a bearing.

In so far as the author's results are new, he has not attempted to show how they compare with the results of previous investigators who were attacking the same problems. This applies particularly to the new relations connecting pressure distribution with eccentricity, such as Equation [25], by means of which conclusions are finally drawn regarding the load-carrying capacity.

From this point of view the most important previous investigation is that of Sommerfeld[3] on which the subsequent work of Harrison and of Howarth[4] was based. I would like to suggest that the author continue his study to the extent at least of obtaining a comparison between his own equations for pressure distribution and those of Sommerfeld. Such a comparison will be very enlightening because of the physical difference in the basic assumptions from which both investigations proceed.

Thus Sommerfeld neglected longitudinal oil flow and considered only the pressures resulting from complex circumferential movements of the oil. Cardullo goes to the opposite extreme, building up his entire theory on the phenomena of the longitudinal flow, and deliberately neglecting all circumferential movements that cannot be described as a uniform-velocity gradient across the film at any one point. This assumption is introduced on the page where the author states, "In order to simplify the theory, let it be assumed, etc."

In the absence of experimental proof the reader is left entirely up in the air and cannot very easily judge whether Sommerfeld's assumption or Cardullo's assumption is nearer to the truth. The latter, of course, may be entirely possible.

To show that there is a real difference, reference may be made to the writer's paper[5] published in 1914 on "The Laws of Lubrication of Horizontal Journal Bearings." Equation [18] of that paper is based upon the same assumption as made by Cardullo, namely, the uniform velocity-gradient assumption; although the principal conclusions of the paper do not involve Equation [18] but are obtained by dimensional analysis, and are therefore entirely free from any specific assumption as to the character of the oil flow. Equation [19] is an expression of Petroff's law for the frictional resistance of a bearing with concentric journal, a relation that may be accepted without question as exact. It seems unnecessary to reproduce the two formulas here. Now it will be noted that upon dividing one by the other a formula is obtained for the relative friction of an eccentric journal as compared to that of a perfectly concentric journal under the same operating conditions (i.e., same load, speed, and oil viscosity). This relative friction may be written

$$R_c = \frac{1}{\sqrt{1 - e^2}} \qquad [34]$$

in which e denotes the eccentricity ratio as defined by Cardullo. The subscript c has been introduced to indicate that this expression is the one that would have been obtained by Cardullo if he had actually worked out the necessary integrations for computing frictional resistance from the shearing stresses corresponding to his own assumption.[6]

From Sommerfeld's theory a similar relation[7] can be obtained which turns out to be distinctly different from Equation [34], viz., using subscript s for Sommerfeld,

$$R_s = \frac{1}{\sqrt{1 - e^2}} \cdot \frac{(1 + 2e^2)}{(1 + e^2/2)} \qquad [35]$$

Comparing Equations [34] and [35] it is seen that $R_c = R_s$ when $e = o$, but that in general R_c is less than R_s. In fact, at the other limit where metallic contact is about to take place so that $e = 1$, Cardullo's friction value will amount to only one-half of Sommerfeld's value.

The mathematical portion of this paper is an interesting application of the theory of longitudinal oil flow. If only some one could combine this analysis with Sommerfeld's analysis of circumferential flow, one might consider that a complete mathematical theory of the cylindrical bearing operating under thick film conditions had been produced. In the meantime every effort should be made to promote experimental research.

L. J. BRADFORD.[8] The author's development of his theory rests on assumptions some of which appear unjustified. These are:

1 That the velocity of the oil film in the plane of rotation is proportional to its distance from the surface of the box. This

would be true if there were no flow due to differences in pressure within the film. There are, however, large differences in pressure in the film, and oil will flow from the higher pressure to the lower. This velocity of flow due to pressure difference must be either added to or subtracted from the velocity due to viscous drag on the journal and will modify the resultant velocity considerably.

2 The assumption that the quantity of lubricant represented by the change of volume of a filament in passing from the region of maximum clearance to that of minimum clearance is squeezed out at the ends of the bearing. Why cannot some of this lubricant flow in the plane of rotation? The probability is that it does.

The error of neglecting circumferential flow due to pressure differences results, among other things, in the curves of axial pressure distribution, as shown in Fig. 6, being much too sharp. When these pressures are measured on a testing machine the curve is found to be much flatter.

In calling attention to the effects of oil grooves upon the carrying capacity of bearings the author is performing a valuable service. This effect is not thought of by the average designers or mechanics, and the more it can be brought to their attention the better. Lubrication of bearings has been a matter of guesswork too long.

H. A. S. Howarth[9] and S. J. Needs.[10] We wish to call attention first to the fact that A. G. M. Michell, in his paper "The Lubrication of Plane Surfaces" published in *Zeit. f. Math. u. Phys.* in 1905, determined mathematically the influence of side leakage upon the load-carrying capacity and upon the friction of flat inclined bearing surfaces of different ratios of width to length. He assumed constant viscosity throughout the film. He examined the square surface and also the one that was three times as long as wide. He also determined in his "Case III" the leakage influence for a very narrow surface by making the same assumptions as to flow that Cardullo does in this paper.

The method employed by Michell will be evident from the following discussion of Reynolds' fundamental equation:

$$\frac{d}{dx}\left(h^3\frac{dp}{dx}\right)+\frac{d}{dz}\left(h^3\frac{dp}{dz}\right)=-6\mu U\frac{dh}{dx}\qquad[36]$$

This is the equation that must be applied fully to journal bearings if the problem of side leakage is to be correctly solved. In it x is measured in the direction of relative motion; z is at right angles thereto and takes account of the width of the film; h is the film thickness; μ is the coefficient of viscosity; U is the relative velocity of the surfaces; and p is the pressure within the film at any point x, z.

Reynolds in his further study of actual cases, such as flat bearing surfaces and Tower's journal bearing, assumed that the second term of Equation [36] could be dropped out. This gave:

$$\frac{d}{dx}\left(h^3\frac{dp}{dx}\right)=-6\mu U\frac{dh}{dx}\qquad[37]$$

which is the basis of the work of Sommerfeld, Harrison, Howarth and others, in the examination of various bearings. This equation permits calculation of the maximum pressures that can be obtained in a film of known shape and thickness. Michell, however, used Reynolds' Equation [36] complete in the study of square and three-by-one surfaces, and obtained the first general correct solution of the problem of side leakage for flat surfaces.

Then in his "Case III" Michell dropped the first term of Equation [36] and used:

$$\frac{d}{dz}\left(h_3\frac{dp}{dz}\right)=-6\mu U\frac{dh}{dx}\qquad[38]$$

for the study of *very narrow surfaces*. He says, "This simple expression may be used as an approximation for slide-blocks whose length is several times greater than their width." By application of Equation [38] Cardullo's final equations can be obtained without any of the elaborate reasoning he used in order to get to the same place. It is doubtful whether Cardullo was familiar with the equations of Reynolds or the work of Michell. However Cardullo applied his reasoning to what has previously been called the 180 deg. "offset" journal bearing, and although that was a relatively simple matter, he has emphasized the relatively low carrying capacities of *very narrow journal bearings*. The main problem is to decide how far his figures are useful, and to see whether a better rule is available.

For a given film, fixed in form and thickness, the application of Reynolds' Equation [37] will give a maximum pressure p that can be developed within the film, neglecting side leakage. Obviously if side leakage is taken into account the maximum pressure cannot reach p. Hence the pressures obtained by Cardullo can be laid aside as useless, when they exceed the maximum pressure predicted by Harrison when using Reynolds' Equation [37]. Cardullo's pressure equation for the midsection of the bearing in direction of motion is, using Harrison's symbols, c = eccentricity factor; $a = D/2$ = journal radius; η = radial clearance:

$$p_c=\frac{3\,\mu\,U\,c\,L^2\sin\Theta}{4\,a\,\eta^2\,(1+c\cos\Theta)^2}\qquad[39]$$

This becomes maximum when

$$\cos\Theta=\frac{1}{4c}\left(1-\sqrt{24c^2+1}\right)\qquad[40]$$

From Harrison the pressure equation applicable to the 180-deg. bearing of the "offset" series is found to be as follows:

$$p_H=\frac{6\,\mu\,U\,a\,c\sin\Theta\,(2+c\cos\Theta)}{\eta^2\,(2+c^2)\,(1+c\cos\Theta)^2}\qquad[41]$$

This becomes maximum when

$$\cos\Theta=-\frac{3c}{2+c^2}\qquad[42]$$

Hence Cardullo's bearing can be compared with the 180-deg. "offset" bearing, for any given eccentricity, by means of the above equations. After finding the maximum p_c and the maximum p_H, by using for each its proper value of Θ, p_H maximum can be equated with p_c maximum and L/D solved for. (L = bearing width.)

Then the relative capacities of the bearings can be found and the results plotted on a chart having as ordinates[11] the term $\frac{W}{\mu N}\left(\frac{\eta}{a}\right)^2$ and as abscissas L/D. Upon such a chart one may plot for $c = 0.3$ curves, based on Michell's study of the square surface and the three-by-one surface, that will show the approxi-

[9] H. A. S. Howarth, Vice-Pres. & Gen. Manager, Kingsbury Machine Works, Inc.

[10] S. J. Needs, Engineer of Tests, Kingsbury Machine Works, Inc.

[11] w = load on the bearing in lb. per sq. in., found by dividing the total load by the product of the journal diameter times the axial width of the bearing.
N = r.p.m. of journal.

mate influence of side leakage for all L/D proportions up to and beyond $L/D = 4$. Such a curve would show that Cardullo's equations are approximate only for very narrow surfaces. Even then they are on the high side; i.e., they give capacities that are greater than the true capacities of narrow bearings found by the correct method.

The range of usefulness of Cardullo's equations depends upon the eccentricity. The greater the eccentricity, the less the range. For example, Cardullo's capacities would not be unreasonable for values of L/D up to those given in the following table:

$c = 0.8$	$L/D = 0.15$
$c = 0.5$	$L/D = 0.42$
$c = 0.3$	$L/D = 0.62$

If bearings usually run with high eccentricities, 0.8 to 0.9 or more, as Cardullo states, then his equations would be needed most for such bearings and would be reasonably correct for values of L/D less than 0.15, very narrow bearings indeed.

What is needed now is the *correct* solution of Reynolds' *general* Equation [36] as applied to journal bearings of known forms and characteristics. It is to be hoped that some one will be able to solve that problem in the near future so that we may not be faced with further approximations that have such a limited range of application as that offered by Cardullo.

E. O. Waters.[12] It is a pleasure to read a paper on lubrication which states in clear and emphatic form the desirable properties of fluid lubricants. In the past, there has been a tendency to overemphasize viscosity, to the disparagement of other qualities of equal importance. This may well be due to the ease with which viscosity may be measured, at least in a comparative way, and the fact that this is the only property of an oil, outside of its density, which has any place in the mathematical analyses that have been developed during the past half-century, and now occupy a secure position in the literature of fluid friction. The trouble with all such analyses is that they assume (*a*) perfect film lubrication, and (*b*) constancy of viscosity, whereas, as a matter of fact, all bearings start up with metal-to-metal contact, many bearings run continuously in the boundary region that borders on metal-to-metal contact; and the numerical value of the viscosity of the lubricant in any given bearing is subject to considerable change due to temperature and localized regions of high pressure.

As a matter of fact, "oiliness," or the tendency to wet metal bearing surfaces at all times, is all-important in the boundary field of lubrication, and deserves further investigation. At the present time, specifications for lubricants are extremely hazy on this point, and there is a tendency for the producers of lubricating oils and greases to disdain a specification that calls for nothing but viscosity, high flash point, low volatility, etc., when they know full well that other properties less easily definable are quite as important. Would it not be well to investigate the surface tensions of lubricants, with the idea of including this among other specifications as a measure of the oiliness or wetting property?

Coming to the mathematical portion of the paper, it is evident at the outset that the author has discarded the classical analysis and followed a distinctly different line of reasoning, basing his equations on the assumption that the pressure in the bearing is caused entirely by axial motion of the fluid. The method followed by Reynolds, Sommerfeld, and others assumes, it will be remembered, that the fluid motion is wholly tangential. Obviously, both lines of reasoning are open to criticism; the classical method neglects the end leakage that occurs in all bearings and is critical in very short bearings, and Mr. Cardullo's analysis gives excessively high pressures for bearings of great length. In fact, Equation [23] of the paper indicates that the unit pressure on a bearing increases as the square of the length so that the total load sustained by a bearing of only moderate length would be of the order of infinity.

A common-sense analysis of the problem, without resort to mathematics, would indicate that at the center of any cylindrical bearing, the oil will be continually dragged from a region of low pressure and large clearance to one of high pressure and small clearance, and in squeezing through this small clearance it will speed up in the direction of least resistance, i.e., along the shortest and steepest pressure gradient. In short bearings, this would be toward the two ends, but in all other cases it would be a composite motion, and in long bearings it would apparently be easier for the oil to "escape" by travelling around the shaft to the low-pressure region, than to flow along it to the distant ends.

A rough comparison of the load capacities obtained by the two methods for a square bearing (length = diameter) may be of interest. Let $e = 0.6$, $w = 3.68$ rad. per sec., $L = 2$ in., $r = 1$ in., $c = 0.001$ in., and $k = 3.4 \times 10^{-6}$ lb-sec. per sq. in., corresponding to 150 sec. Saybolt. Then according to Equation [22], the unit pressure at any point is

$$P = \frac{6 \times 3.4 \times 10^{-6} \times 3.68}{0.000001} \times \frac{0.6 \sin \theta}{(1 + 0.6 \cos \theta)^3} (Lz - z^2)$$

$$= 75 \times \frac{0.6 \sin \theta}{(1 + 0.6 \cos \theta)^3} (Lz - z^2)$$

The total pressure on a filament of 1 in. width measured circumferentially, extending from end to end of the bearing and from the surface of the journal to that of the bearing, is:

$$2 \int_0^{\frac{L}{2}} P dz = 75 \times \frac{0.6 \sin \theta}{(1 + 0.6 \cos \theta)^3} \times \frac{L^3}{6}$$

$$= 100 \times \frac{0.6 \sin \theta}{(1 + 0.6 \cos \theta)^3}$$

According to Tables 1 and 2, this corresponds to a carrying capacity of $F = 83.5$ lb. per inch of circumferential length of bearing. Since the bearing diameter is 2 in., and the pressure must be sensibly zero over one half the circumference, from the point of closest approach around to the oil groove, Fig. 6, the total carrying capacity is $83.5 \times \pi = 263$ lb.

The problem of the partial bearing has been attacked by Howarth[13] according to the classical method. Here, the carrying capacity depends not only on the variables considered in Cardullo's analysis, but also upon the angle between the load line and the entering and leaving edges of the bearing. For a "central" bearing, in which the above angle is 90 deg., the carrying capacity may be obtained from his Fig. 30, and is found to be 1.2 lb. per sq. in. of projected area per r.p.m. Since the assumed speed is 3.68 rad. per sec. for the oil, or $\frac{3.68 \times 60 \times 2}{2 \pi}$ = 70.3 r.p.m. for the journal, and the projected area is 4 sq. in. the total carrying capacity of the bearing would be $1.2 \times 4 \times 70.3 = 338$ lb.

Time and space do not permit of a further study along these lines, but it may be assumed that the figure of 338 lb. should be considerably reduced because the load line is offset upward of 47 deg. from the central position. (See Fig. 4.) At any rate the

[12] Assoc. Prof. of Mechanical Engineering, Yale University, New Haven, Conn.

[13] "A Graphical Study of Journal Lubrication. (Part II)" Trans. A.S.M.E., vol. 46, p. 809.

load ratings for the square bearing as calculated by the two methods are roughly equivalent, but for any shorter bearings the Cardullo formulas would give much smaller values than those obtained by the classical method. This would seem to be in agreement with common sense, and perhaps some empirical formula like [33] in the paper may be devised to cover both long and short bearings. However, the writer believes that it should be held in abeyance until well corroborated by experimental data.

Author's Closure

Most of the discussion of this paper is contributed by men whose knowledge of mathematics and of the literature of bearings far exceeds that of the author. It is not necessary to point out that the author's theory is not complete and correct, because it is pointed out in the paper itself.

In developing his theory the author has made certain assumptions not in accordance with the facts, but no other bearing theory accords with facts, and even Reynolds' fundamental equation, which has hitherto defied a general solution, and which is discussed by Messrs. Howarth and Needs, accords only with geometrical assumptions which are never realized in practice.

There are in general two ways to attack a scientific or engineering problem. The first is to develop a general equation, such as Reynolds' fundamental equation, and then *if possible* to solve this equation by purely mathematical manipulation. If the general equation is correct and the solution is obtained, we have an answer which may or may not be approximately correct, depending upon how important the factors are which were necessarily eliminated in order to obtain a manageable general equation. For instance, the factors eliminated from Reynolds' general equation are variations in diameter of the shaft and the box, bending of the shaft, lack of parallelism of the axes of the shaft and the box, and local irregularities in the surface of the box produced by variations in the hydrostatic pressure. Even though we had a solution of Reynolds' general equation, we would still be a long way from answering the question of the best design for a bearing.

While the general method is favored by most men of high mathematical attainments, the author prefers to attack a problem in detail, examining and analyzing each element separately and in its relation to the other elements, in order to get a vivid physical concept of the problem. To a mathematician this appears to be a clumsy and inelegant method, but it is exactly the method which the practical engineer must use when he is dealing, not with mathematical concepts, but with imperfect materials machined to imperfect forms, and acted upon by forces which distort the forms from those to which the materials were originally machined.

Frankly, this paper is not a presentation of a mathematical theory of a bearing. It is, instead, a general discussion of the phenomena occurring in thick film lubrication of cylindrical bearings, in which the mathematical theory is brought into the picture, not to obtain an arithmetical solution of the problem, but to illuminate the phenomena which occur and to make clear their interrelation.

While much excellent work has been done on the subject of bearings, most of it has been so purely empirical as to be of value only in the immediate region investigated, or else so purely theoretical that the great majority of designers are incapable of comprehending it, the mathematics being divorced as far as possible from the physical concepts which they express.

The author has endeavored to make his paper helpful to the average designer of mediocre mathematical attainments, and to link each step of the mathematical development with the physical concept with which it is associated. In order to do this, a simplified theory is necessary, and the author has chosen the particular simplification of the general theory which lends itself most readily to his purpose.

The author would also like to point out that 95 per cent of the literature on the theory of thick film lubrication is practically inaccessible to the great majority of the members of the Society either because it is published in transactions or periodicals which are procured only with difficulty or because it is available only in an unfamiliar language. The author feels, therefore, that this paper and the accompanying discussion may be of some value in calling the attention of interested members of the Society to a body of literature which exists, and which is continually growing.

The author feels strongly that this body of literature should be rewritten in such form as to make it available, comprehensible, and useful to that body of engineers who have to do with the design of machine bearings and whose mathematical attainments, like those of the author, are limited to elementary calculus.

The author wishes there was available such a book, similar to the most admirable book on bearings compiled some years ago by one of our members, Mr. L. P. Alford, which, however, dealt with the subject almost entirely from the empirical standpoint and practically ignored the various theories of lubrication.

For lack of such a book most bearings are designed by purely empirical formulas which are useful within limited ranges, but which do not meet the needs of present-day engineering requirements.

Cutting Tests With Cemented-Tungsten-Carbide Lathe Tools[1]

By T. G. DIGGES,[2] WASHINGTON, D. C.

This investigation was made for the purpose of developing a method of testing cemented-tungsten-carbide lathe tools under heavy duty and to extend to the new cutting material some of the laws originally developed by Taylor and his associates for cutting with carbon- and high-speed-steel tools. Relations were determined between the speed, feed, depth of cut, and tool life for a selected form and size of tool. All tests were made dry in cutting 3.5 per cent nickel-steel forgings, heat-treated to give tensile strengths within the range of 85,000 to 110,000 lb. per sq. in. The results are presented in both graphic and tabular forms.

CEMENTED-tungsten-carbide tools were first placed on the market on a commercial basis in Europe in 1926 and in the United States several years later. The rapid development of this material during the past year has made possible its extensive use for tools throughout this country and abroad.

The records of production with these tools have already shown that this new cutting material will occupy a most important place in our industrial life.

The experiments described in this report relate primarily to a study of lathe-tool performance as affected by the conditions of cutting, such as variations in speeds, feeds, and depths, while the composition, the size, and the form of the tools and cutting materials were not varied. The investigation was for the purpose of developing a method of testing tungsten-carbide tools under heavy duty and to establish some of the laws of cutting which define the approximate relations between tests of short duration, which might be made in the laboratory, and long-time cutting required in practical service. The need of such information is shown by the large number of inquiries received by the Bureau of Standards from consumers.

Previous Investigations

No attempt will be made to review the abundant literature published since the introduction of tungsten carbide as a cutting material. The articles published have dealt primarily with outstanding production records and other phases not directly related to the field to be covered. Such data may be used to advantage, and important technical publications containing information on the subject under discussion will be referred to in the individual sections of this report.

Methods of Tests—Equipment

A 36-in. heavy-duty engine lathe, driven by a 40-hp. 220-volt d.-c. shunt motor, was selected. (See Fig. 1.) A Link Belt chain was used to insure a positive drive. Accurate speed control of the work piece was secured by using the several gearing ratios of the lathe and by changing the speed of the motor with a variable resistance in the field circuit. Experiments showed that it was necessary to increase the rate of speed of the motor in order to prevent excessive slowing down or stalling under heavy loads.

A special tool holder was designed to give ample support to the test tool near the cutting edge. This was firmly clamped in the four-bolt tool-post holder shown in Fig. 1.

A "live center" (tailstock) containing a ball bearing and having the form and dimensions shown in Fig. 2 was used instead

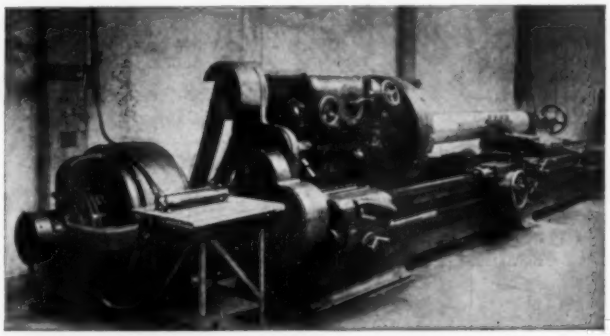

Fig. 1 Lathe Used in Tool Tests

of the customary "dead center." Its insertion required considerable time and labor, but it avoided lubrication troubles common with the "dead center."

A single-pointed cutting tool was selected, and its form was similar to that commonly employed for heavy-duty roughing work. Its form and dimensions, as shown in Fig. 3, consisted of tungsten-carbide tips approximately 0.18 in. thick, 0.31 in. wide, and 0.87 in. long, copper-brazed on a shank 0.5 in. wide, 1 in. thick, and 7 in. long. The tools had a plane angle of 90 deg. and were ground to 6 deg. front and side clearance, 0 deg. back slope, 14 deg. side slope, 10 deg. back side relief, and the radius of the nose was 0.0625 in. The edge of the tool from this arc along its cutting edge was ground to a contour of 1.75 in. radius for 0.4375 in. All tools were hollow ground to a depth of 0.003 to 0.006 in. at approximately 0.25 in. from the cutting edge of the tools. Special grinding wheels of silicon carbide were used for grinding the tools.

The tools used in this investigation were manufactured by the Carboloy Company, Inc., by certain sintering operations in which the fine particles of tungsten carbide were cemented firmly together with cobalt, and the material is referred to as cemented

tungsten carbide to differentiate it from the cast product. Chemical analyses were made on two lots of tungsten-carbide tools that were supplied at different times. Table 1 shows that the tools were quite uniform.

Procedure

From five to eight tools were tested for most of the conditions investigated, and all tests were made in sequence. For example, in the study of the effect of feed on tool performance, one tool was tested at each of the selected feeds in the series, a second tool was tested at each of the same feeds, and this procedure was continued until the desired number of tools had been tested for each condition. From one to three tests were made with each tool, but no tool after being reground was used under the same conditions of test as those under which it had formerly been tested. Only average values are used for comparisons in this report.

Testing tools in sequence has long been practiced and tends to minimize variations in results arising from inhomogeneities in the metal being cut. The pieces upon which the cuts were taken, referred to as forgings, were originally from 10 to 12 in. in diameter and from 8 to 10 ft. in length. In some cases the forgings were cut to diameters as small as 4.5 in. in the cutting tests. Average mechanical properties were determined on longitudinal specimens cut from the forgings so as to represent the average metal removed during cutting. The chemical composition, heat treatment, tensile properties, and Brinell hardness of the forgings are given in Table 2.

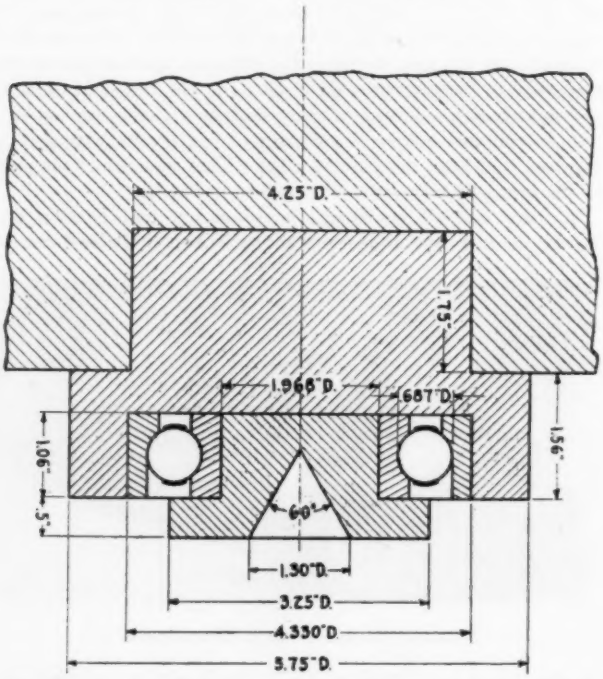

Fig. 2 Type of Tailstock Center Used in Lathe Tests

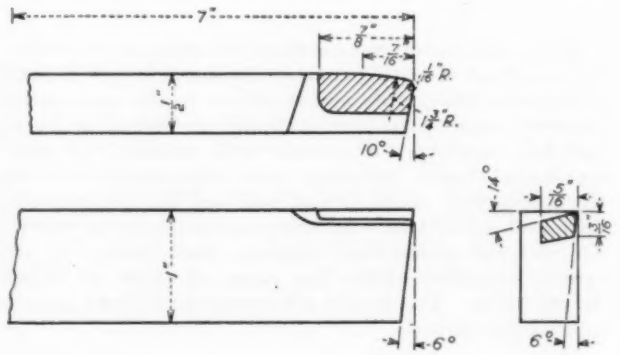

Fig. 3 Size and Form of Tool Used in Lathe Tests

In making a cutting test the tool was clamped so that its side was at right-angles to the longitudinal axis of the forging, with the end of the nose on dead center. The lathe was then set at the desired feed, the tool at the required depth, and the speed of the lathe adjusted to give the forging the desired peripheral speed. The tool was fed by hand until the desired cut was reached, after which the automatic feed was thrown in and the time recorded. The speed of the forging decreased when cutting began, but was quickly adjusted to bring it back to its original value. Before starting any test care was taken to remove any glazed surface on the forging caused by the breakdown of the previous tool or any particles of the tool that might have become embedded in the forging.

All tests were run dry, and the cutting speed, feed, and depth

of cut were varied, depending upon the purpose of each series of tests.

Tool Failure

A groove was formed on the top surface of the tool near the "leading edge" soon after the tool started to cut. This depression became greater as the test progressed until a condition was finally reached when the wear was sufficient to cause a small

Fig. 4 Depressions Worn on Top Surfaces of the Tools During Tests
(All tools had failed except tool shown on extreme left.)

Fig. 5 Wear on Front of Tools During Test
(All tools had failed except tool shown on extreme left.)

section to chip or break out of the working portion of the tool. This "end point" usually resulted in a glazed surface on the test forging and was often accompanied by a splitting of the chip, which gave an additional indication of tool failure. Thus there was a very definite end point and one that could be recognized without much difficulty. In some of the experiments, especially those of the most severe conditions of cutting, this end point was often quickly followed by, if not simultaneous with, tool breakage which would leave doubt as to the time of tool failure. Such doubtful tests were discarded in these experiments. In some cases it would have been possible to continue to cut after the described condition was reached, but only at the expense of badly broken tools. All cutting results given in this report were obtained by the "end-point" method described. The wear on the top and front surfaces of the tools at the time of failure is illustrated in Figs. 4 and 5.

The appearance of the forging at the time of failure of the tungsten-carbide tools was very similar to the appearance of a forging when a high-speed-steel tool fails under the so-called "lathe breakdown test." A glazed surface was produced on the forging at the bottom of the cut at the time of tool failure, as is shown in Fig. 6.

Effects of Cutting Speed on Tool Life

It is a well-known fact that the cutting speed of a high-speed-steel lathe tool is dependent upon the quality, composition, and heat treatment of the tool and on the properties of the metal cut, as well as upon the size and form of tool, feed, and depth of cut. It appeared reasonable to assume that the cutting speed of cemented-tungsten-carbide lathe tools should depend upon approximately the same variables as high-speed-steel tools, and it was upon this basis that the experiments were performed.

The results of tests at different speeds with a feed of 0.031 in. per revolution and depth of 0.1875 in. are summarized in Table 3 and Fig. 7. Fig. 7 shows that there was a continuous increase in the life of tungsten-carbide tools as the cutting speed was decreased. Within the life range of 9 to 156 minutes the experimental results may be represented by the empirical equation

$$VT^n = c \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

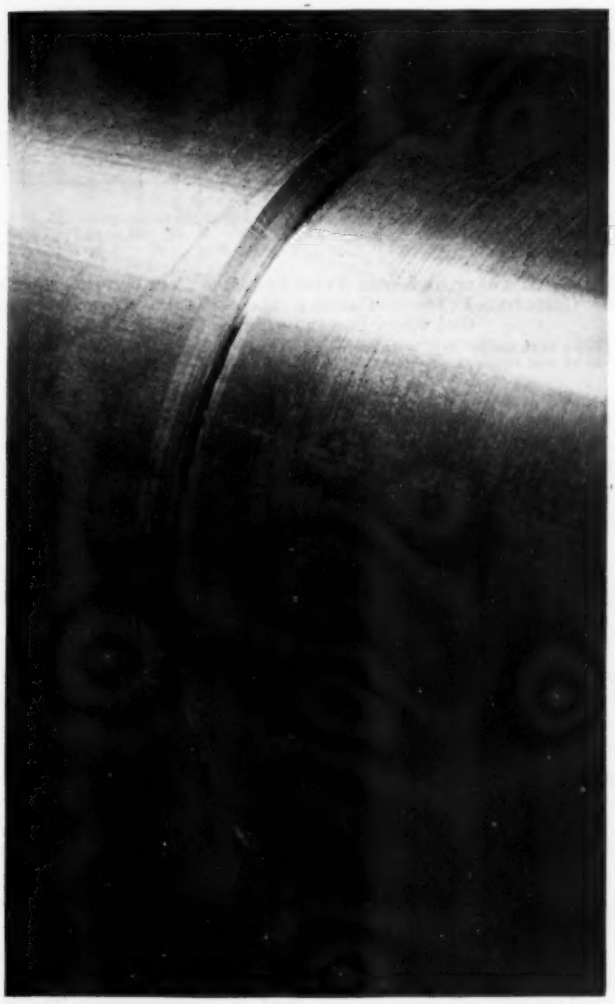

Fig. 6 Appearance of Test Forging at Time of Tool Failure
(Note the glaze at the bottom of the cut.)

in which V = the cutting speed in feet per minute
T = the tool life in minutes
c = a constant which is dependent upon the cutting conditions other than speed; it should vary with the form and size of tools, material cut, nature of tools, feed, and depth of cut
n = constant.

Taylor[3] found the effect of cutting speed on the tool life of

high-speed steels could be represented by Equation [1]. This empirical relationship between tool life and cutting speed with high-speed-steel tools was recently confirmed by the Lathe Tool Research Committee[4] and by tests conducted at the Bureau of Standards,[5,6] and by Ripper and Burley.[7]

Taylor[3] reported cutting tests on carbon steels having a tensile strength of about 70,000 lb. per sq. in. with tools of definite size and shape made from steel containing about 1.9 per cent carbon, 8.5 per cent tungsten, and 2 per cent chromium. He found the value $n = 1/8$ and $c = 90$, but stated, "We have made a number of experiments . . . with different qualities of steel and find that approximately the same relation exists between the duration of cut and cutting speed for steels of different degrees of hardness. This statement, however, does not apply to cast iron."

Not all investigations have confirmed Taylor's value of the exponent n. Ripper and Burley[7] reported the value of $n = 1/13$, and French and Digges[8] in cutting tests with modern high-speed tools cutting $3\frac{1}{2}$ per cent nickel steel of about 100,000 lb. per sq. in. tensile strength reported $n = 1/7$ for roughing conditions (heavy duty) and $n = 1/10$ for finishing cuts (light duty).

Schlesinger,[9] in cutting experiments carried out at the Technological Institute at Berlin with high-speed steel and superhard metal tools in cutting a steel of approximately 100,000 lb. per sq. in. (Brinell number of about 190), found that the cutting-speed–tool-life curves for the super-hard metals had the same characteristics as those of high-speed steel. His data show that the relations between tool life and cutting speed for sintered-tungsten-carbide tools, where the cross-section of the chip was 0.158 by 0.039 in., could be closely represented by Equation [1] when $n = 1/4.3$. In another set of experiments which appear to have been carried out under the same test conditions, it was found that $n = 1/7.1$. With high-speed-steel tools n was found to be equal to about $1/8.3$, which is in close agreement to the value reported by the Bureau of Standards for roughing tests.

Examination of the results summarized in Fig. 7 shows that the experimental values obtained for sintered-tungsten-carbide tools were approximately represented by Equation [1] with $n = 1/5$. Therefore, the equation

$$VT^{1/5} = c \qquad [2]$$

was used for all computations in this report involving the relation between the cutting speed and tool life. There was a close concordance between the experimental results and the calculated values, and Equation [2] should be sufficiently accurate for all practicable purposes except for extrapolating for very long tool life from tests of short duration. It is of interest to note that this law as originally developed by Taylor and his co-workers was confirmed with the cemented-tungsten-carbide lathe tools

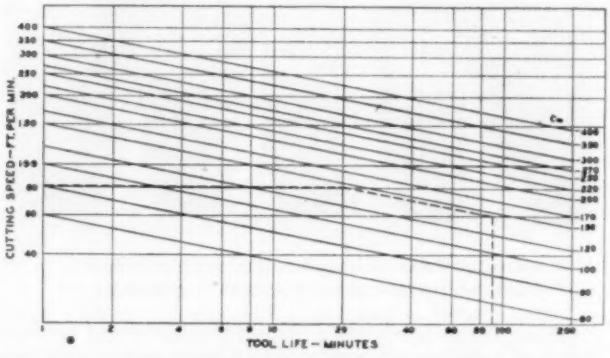

FIG. 8 CHART GIVING RELATION BETWEEN CUTTING SPEED AND TOOL LIFE

(Lines drawn according to Equation $VT^{1/5} = c$, in which V = cutting speed, T = tool life, c = constant.)

for duration of cut between 9 and 156 minutes under conditions widely different from those of Taylor's experiments.

Equation [2], which expresses the relation between tool life and cutting speed, is represented graphically by straight lines when logarithmic rectangular coordinates are used. The chart reproduced in Fig. 8 is of a convenient form for computing the life of tools at various speeds and makes it simpler to interpolate between the values of the constant c shown on the chart than would be the case with the curves obtained with Cartesian coordinates.

EFFECT OF FEED AND DEPTH OF CUT ON THE CUTTING SPEED

It is not practicable to select a single cutting speed for lathe-tool testing varying widely in either feed or depth of cut because of the expense of the large amount of material that would be involved and the time required to make such test. The cutting speed has already been shown to have an empirical relation to the tool life at a given feed and depth, so that in the study of the effects of feed and depth on tool performance the cutting speed was also varied. In general, cutting speeds giving an average tool life from 10 to 30 min. were selected, and then the

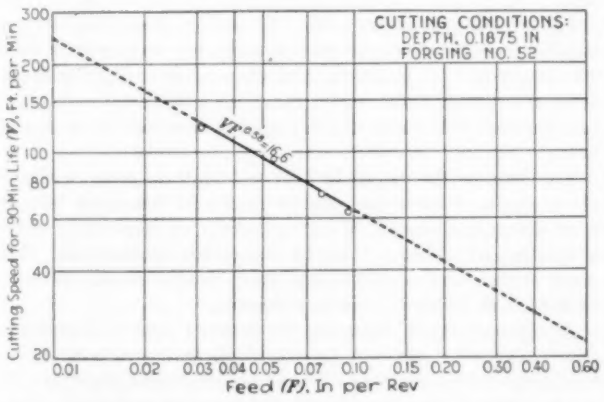

FIG. 9 SUMMARY OF LATHE TESTS SHOWING EFFECT OF FEED ON CUTTING SPEED FOR A 90-MIN. TOOL LIFE

(Tests were made "dry" with form and size of tool shown in Fig. 3. Properties of forging given in Table 2. Line drawn according to Equation $VF^{0.58} = 16.6$, in which V = cutting speed for 90-min. tool life, ft. per min.; F = feed, in. per rev.)

cutting speeds for the desired tool life were computed by means of Equation [2].

Two series of tests were made with the cemented-tungsten-carbide tools in order to establish the relations between the cutting speed, feed, and depth of cut. One was made with a constant depth of cut of 0.1875 in. and feeds ranging from 0.031 to 0.096 in. per revolution, and the other with a constant feed of 0.031 in. per revolution and depths of cut ranging from 0.125 to 0.5625 in.

The results of the tests made with a constant depth of cut and variable feeds are given in Table 4, and the cutting speeds for a 90-min. tool life with the different feeds used in the experiments are summarized in Fig. 9. As shown in Fig. 9, the relation between the cutting speed and the feed for a given tool life at a constant depth of cut may be represented approximately by the relation

$$VF^m = c_1 \quad \ldots\ldots [3]$$

in which V = cutting speed in feet per minute for a selected tool life
F = feed in inches per revolution
c_1 = constant
m = constant

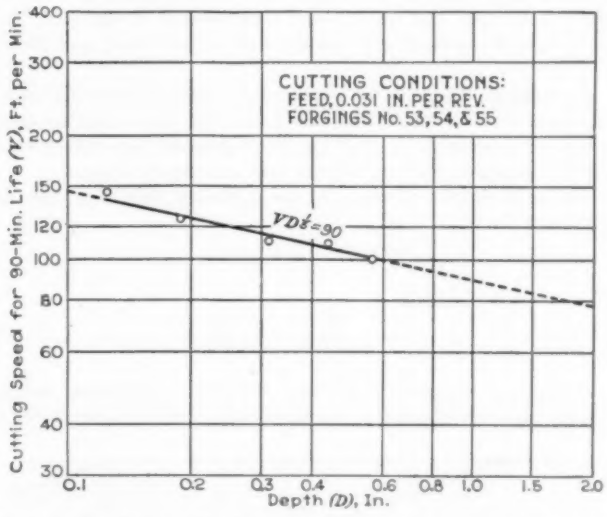

FIG. 10 SUMMARY OF LATHE TESTS SHOWING EFFECT OF DEPTH OF CUT ON CUTTING SPEED FOR A 90-MIN. TOOL LIFE

(Tests were made "dry" with form and size of tool shown in Fig. 3. Properties of forgings given in Table 2. Line drawn according to Equation $VD^{1/5} = 90$, in which V = cutting speed for 90-min. life, ft. per min.; D = depth of cut, in.)

When operating with cutting speeds for a selected 90-min. tool life at a 0.1875 in. depth of cut in cutting 3.5 per cent nickel-steel forging having a tensile strength in the neighborhood of 85,000 lb. per sq. in., the exponent m was found to be 0.58, with c_1 equal to 16.6. Substituting these results in Equation [3] gives

$$VF^{0.58} = 16.6 \quad \ldots\ldots [4]$$

The detailed results as recorded in Table 4 show a surprisingly close agreement between the individual tool performances. In a majority of the tests this variation was no greater than that ordinarily found when testing high-speed-steel lathe tools under heavy duty.

The results of the cutting tests made with a constant feed and variable depths are given in Table 5. The cutting speeds for a 90-min. tool life with the different depths used in the experiments are summarized in Fig. 10. The results show that there was a continuous increase in the cutting speed with a decrease in depth of cut and that the relation between the cutting speed and depth of cut with a constant feed and given tool life may be represented by the equation

$$VD^p = c_2 \quad \ldots\ldots [5]$$

in which V = cutting speed in feet per minute for a selected tool life
D = depth of cut in inches
c_2 = constant
p = constant.

It was found that p was equal to 0.2 and that c_2 was equal to 90, for a 90-min. tool life, and with a feed of 0.031 in. per revolu-

tion and depths of cut varying from 0.125 to 0.5625 in. Substituting these results in Equation [5] gives

$$VD^{0.2} = 90 \quad \ldots\ldots [6]$$

An examination of Fig. 10 shows that there was a close agreement between the experimental and calculated values over a wide range of depths of cut.

As already stated, the cutting speed for a given tool life is dependent upon the quality and composition of the tool, the properties of the metal cut, size and form of tool, feed, and depth of cut.

In these experiments the quality and composition of the tools, size and form of tools, and the metal cut were kept as near constant as possible so that the cutting speed for a given tool life was dependent only upon the feed and depth of cut.

From Equations [4] and [6] for a 90-min. tool life, there is obtained

$$VF^{0.58}D^{0.2} = K = 12 \quad \ldots\ldots [7]$$

or

$$V = \frac{K}{F^{0.58}D^{0.2}} = \frac{12}{F^{0.58}D^{0.2}} \quad \ldots\ldots [8]$$

The equations given in this report check experimental values closely and can be used as the basis for computing speeds for a

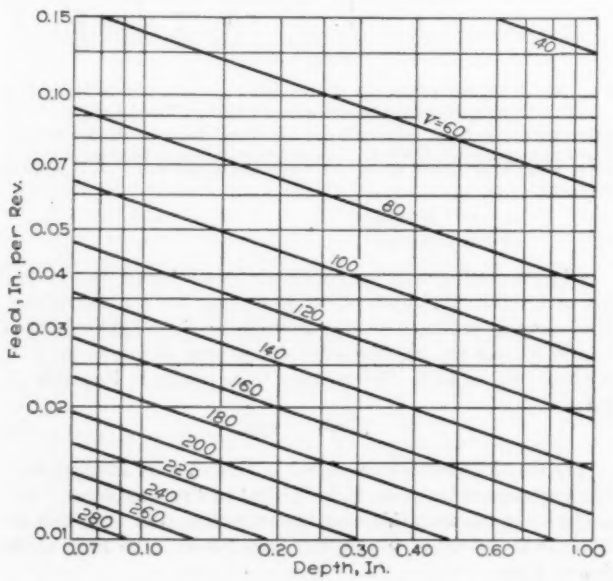

FIG. 11 CUTTING SPEED-FEED-DEPTH CHART FOR SELECTED SIZE AND FORM OF TOOLS AND CUTTING MATERIAL USED IN EXPERIMENTS

(This gives cutting speed for 90-min. tool life in dry turning 3.5 per cent nickel steel of approximately 85,000 lb. per sq. in. tensile strength at various feeds and depths. The maximum feed and depth values as shown on chart are greater than those that can be used with 1/2-in. by 1-in. cemented-tungsten-carbide tools. Refer to text for discussion of use of chart.)

selected tool life under varying conditions, provided the size, form, quality, and composition of tools and the type of cutting material herein described are used. If the tool life is known at some one speed, feed, and depth of cut, these computations require only the use of Equations [2] and [7]. The computations necessary in applying Equations [2] and [7] are, however, tedious because of the form of Equation [7], and to avoid these computations the chart reproduced in Fig. 11 was constructed. This chart is adopted for the reading of the various cutting speeds permitting a 90-min. tool life with various combinations of feeds and depth of cut. With the logarithmic rectangular coordinates used for depth of cut and feed, the cutting speed V (shown on the chart, Fig. 11) for 90-min. tool life is represented by straight lines.

In using this chart, find the intersection of the desired feed and depth coordinates. This point of intersection will usually fall between the sloping lines representing the cutting speed. This value will give the approximate cutting speed V for a tool life of 90 min. The cutting speed for a tool life within the range of 1 to 200 min. may be obtained from the charts reproduced in Figs. 11 and 8 or by Equations [7] and [2].

For example, if it is required to compute the cutting speed for a 90-min. tool life with a feed of 0.08 in. per revolution and 0.5 in. depth of cut, from Fig. 11 it will be seen that the 0.08 in. per revolution feed and 0.5 in. depth coordinates intersect at the speed line corresponding to 60 ft. per min. Now, if the cutting speed for 20-min. tool life with the same feed and depth of cut is desired, there is obtained the value of 81 as given by the chart shown in Fig. 8. This latter value is obtained by finding the intersection of the abscissa representing a tool life of 90 min. (follow the dotted line in Fig. 8) with the ordinate representing a cutting speed of 60 ft. per min., then by interpolating by following the straight line (shown in Fig. 8 as $c = 150$) until this line intersects the abscissas representing a tool life of 20 min.

Fig. 11 was constructed with the lines representing the permissible cutting speeds for 90-min, tool life, ranging from 40 to 280 ft. per min. at intervals of 20 ft. per min. Cutting speeds other than those shown on the chart for a 90-min. tool life may be estimated with a reasonable degree of accuracy by extrapolation.

The limits of the values for feed and depth as given in Fig. 11 are in excess of those that can be used with 0.5-in. by 1-in. cemented-tungsten-carbide tools. However, it is possible to use a wide range of feeds and depths of cut with this size tool. This chart should also be applicable (with modifications) to larger tools than those used in the experiments.

As already stated, Equation [7] does not take into consideration changes in size and form of tools and variations in materials cut. The need of such tests becomes immediately apparent in order to extend the relations between the relatively short-time laboratory test of this new cutting material to its wide field of industrial work.

As shown by Equation [7], the cutting speed is not affected equally by changes in feed and depth of cut. A higher cutting speed is more closely associated with a deep cut and fine feed than with a corresponding combination of coarse feed and shallow cut. Equations [2] and [6] show that the exponents n and p, expressing the relation between cutting speed and tool life and the cutting speed and depth of cut, are equal.

GENERAL COMMENTS ON THE LATHE TESTS

Despite the fact that cemented tungsten carbide contains appreciable proportions of cobalt, it is a relatively brittle material, and for this reason the cutting tools must be well supported. For these tests the carbide tips were joined to the tool shank by copper-brazing in a hydrogen atmosphere. Hoyt[10] stated: "It has been found that tungsten-carbide tips which are rigidly welded to the shank are only too apt to come off, either directly after the tool is made or after being put in service. This is due to thermal stresses which are set up by temperature changes and differences in the coefficients of expansion of the carbide and the steel. This circumstance accounts for the popularity of copper-brazing, because here the thin layer of copper affords a soft cushion which absorbs such stresses without

[10] S. L. Hoyt, "Tungsten-Carbide Tools Most Remunerative of Production Jobs," *Iron Age*, vol. 124 (1929), p. 1173.

transmitting them to the carbide tip. On the other hand, copper softens at elevated temperatures, so that it is necessary, in the design of the tool, to remove the joint far enough away from the cutting edge so that it does not get dangerously hot during operation."

This method of attaching the carbide tip was satisfactory for most of the conditions used in the cutting tests, although premature failure in several tests resulted because of the rupture of this bond.

The heaviest cuts used with the 0.5-in. by 1-in. tools were probably greater than those that could be used in ordinary shop practice where cost due to tool breakage becomes important. The carbide tips of the tools were reduced in size by grinding and weakened accordingly, so that most of the tool breakage was confined to the heaviest cuts with tools that had been reground. The test showed that the tools could be used under relatively heavy duty provided they were properly supported and not subjected to vibration.

The forces on a lathe tool, while cutting, are practically independent of the cutting speed and are dependent upon the cross-section of the chip. It is evident from this principle that tungsten-carbide tools should be used at relatively high speeds and for light cuts in order to keep tool breakage at a minimum. As shown by Equation [2], the cutting speed varies as the $^1/_8$th power of the tool life. This indicates that a small change in cutting speed causes a correspondingly large change in the tool life, so that the higher cutting speeds are obtained only at the expense of shorter tool life. The most economical cutting conditions must, therefore, be a compromise between several factors, such as increase in cutting speed with decrease in tool life and tool breakage, in order to remove the maximum amount of metal in the minimum time at the least cost.

Some idea of the relation between the cutting speeds associated with tungsten-carbide tools and high-speed-steel tools may be obtained from the cutting-speed–tool-life curves reproduced in Fig. 12. Attention is directed to the fact that the two curves were not made under identical conditions of cutting, and only a general comparison can be made from these results. For example, the tungsten-carbide tools are larger than those used in the high-speed-steel experiments, and the tool angles are different for the two types of tools.

The high-speed-steel tools were of the 18 per cent tungsten type, quenched in oil from 2400 deg. fahr., and tempered at 1100 deg. fahr. These tools were 0.25 in. by 0.5 in. in size and were ground to a front and side clearance of 6 deg., side slope of 8 deg., back slope of 14 deg., and a nose radius of 0.125 in. The cutting materials, as shown in Table 2, had approximately the same chemical and physical properties, but, as already pointed out, it does not necessarily follow that the two forgings have the same cutting properties. Both forgings were of the 3.5 per cent nickel type, heat-treated to give a tensile strength of about 85,000 lb. per sq. in.

Fig. 12 shows that considerably higher cutting speeds (under certain conditions) were obtained with the tungsten-carbide tools than with the high-speed-steel tools. Also, the slopes of the straight lines representing the relations between cutting speed and tool life with the logarithmic system of coordinates were different for the two types of tools. The slope of the curves obtained with the tungsten-carbide tools was greater than that obtained with the high-speed-steel tools. This means that the two curves tend to approach each other, and the differences between the cutting speeds of the two materials decrease with increase in tool life. If these curves are extrapolated to an extremely long tool life, then the curves will cross, and the high-speed-steel tools would show higher cutting speeds than the tungsten-carbide tools. However, such long-time cutting cannot be extrapolated with any degreee of accuracy from the present empirical equations, and it is also doubtful if cutting conditions resulting in such long tool life would ever be practicable in modern shops from an economical standpoint.

While the tungsten-carbide tools were considerably superior to those of high-speed steel in cutting 3.5 per cent nickel-steel forgings of about 85,000 lb. per sq. in. tensile strength, it does not follow that the same degree of superiority will be obtained under widely different cutting conditions, especially where heavy feeds and deep cuts are used. Therefore, it is necessary to know exactly the cutting conditions in order to make a comparison of the two types of tools.

No direct indication of the performance of the tungsten-carbide

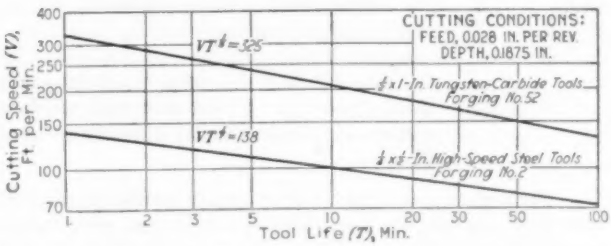

FIG. 12 SUMMARY OF RELATION BETWEEN CUTTING SPEED AND TOOL LIFE WITH TUNGSTEN-CARBIDE AND HIGH-SPEED-STEEL LATHE TOOLS

(Tests were run "dry" with the size and form of tools shown in report. Properties of forgings given in Table 2. For cemented-tungsten-carbide tools, line drawn according to Equation $VT^{1/8} = 325$. For high-speed-steel tools, line drawn according to Equation $VT^{1/8} = 138$, in which V = cutting speed, ft. per min.; T = tool life, min.)

tools could be detected by the types of chips produced in the lathe tests. In general, the chip came off in very long ribbons during the first part of the cut, and then became shorter with more curl as the cutting time increased, until a short time before tool failure the chips were approximately 0.5 to 1 in. in length. While these chips were characteristic for some of the conditions employed, especially with tools tested on forging No. 52, they were not characteristic of the tools tested under conditions of varying depths of cut on forgings Nos. 54 and 55. In the latter case, the long chips often continued until tool failure.

The power required in cutting was determined in all of the lathe tests with tungsten-carbide tools and was determined at frequent intervals throughout the life of the lathe tools, so that only average values were obtained. The instruments used, however, did not permit determinations of the fluctuations or the maximum momentary power consumption. The results given in Table 3 show that, at constant feed and depth of cut, the power was approximately proportional to the cutting speed. The exact relations between the feed and depth of cut and the power consumed cannot be established at this time. The results given in Tables 4 and 5 show that there was an increase in the power with increase in feed or depth. However, as already pointed out, the feed and depth experiments were not made at a constant speed, so that the magnitude of the changes in power due to changes in feed or depth cannot be established from the limited number of tests made. The power determinations are included with the test results in order to show that it is necessary to have machines equipped with powerful driving units in order to utilize the full capacity of tungsten-carbide tools.

SUMMARY AND CONCLUSIONS

1 The primary object of this investigation was to develop a method of testing tungsten-carbide lathe tools under heavy duty and to extend to the new cutting material some of the empirical laws originally developed by Taylor and his associates for rough turning with carbon- and high-speed-steel tools.

2 The so-called lathe breakdown test for high-speed steels was found applicable for testing cemented-tungsten-carbide tools under heavy duty.

3 The characteristics of the cutting-speed–tool-life curves for tungsten-carbide tools were similar to those of high-speed-steel tools.

4 In dry rough turning 3.5 per cent nickel steel of about 105,000 lb. per sq. in. tensile strength, with a constant feed, depth of cut, tool size, and form, the relation between cutting speed and tool life within the life range of 9 to 156 min. may be represented by the empirical equation

$$VT^n = c$$

where V = the cutting speed in feet per minute
T = the tool life in minutes
n = constant = $1/8$
c = constant which is dependent upon the conditions of cutting. It will vary with the form and size of tools, materials cut, feed, and depth of cut.

5 For a given area of cut, higher cutting speeds are obtained with deep cuts and fine feeds (within limits) than with shallow cuts and coarse feeds.

6 The relation between cutting speed, feed, and depth of cut in terms of the experimental conditions may be represented by the empirical equation

$$VF^{0.48}D^{0.2} = K = 12$$

in which V = the cutting speed for a selected tool life
F = feed in inches per revolution
D = depth of cut in inches
K = constant = 12 for the experimental conditions.

7 Higher cutting speeds are obtained with cemented-tungsten-carbide tools under certain conditions of cutting than with high-speed-steel tools.

8 Cemented-tungsten-carbide tools are brittle, but when properly supported will produce excellent results under certain cutting conditions.

9 High cutting speeds with relatively fine cuts are more favorable to the successful application of tungsten-carbide tools than heavy cuts at slower speeds.

10 Machines capable of operating at high speeds with powerful driving units are necessary to utilize the full cutting capacity of cemented-tungsten-carbide tools.

Acknowledgments

The author acknowledges the assistance and suggestions of Dr. S. L. Hoyt and W. E. Smith. The Carboloy Company, Inc., donated all tungsten-carbide test tools and the majority of test forgings.

Grateful acknowledgment is also due to Dr. R. L. Dowdell, senior metallurgist, for his aid and constructive suggestions in the presentation of the test data, to W. V. Magruder, Jr., laboratory aid, and C. F. Raab, machinist, formerly of the Bureau of Standards, for their assistance in assembling the equipment and for carrying out many of the tests.

Discussion

C. G. Williams.[11] At the present time, all of the noise about cemented-tungsten-carbide tools is in the nature of a selling propaganda and a smoke screen, as it were, to hide the inherent characteristics that at the present time prevent tungsten carbide from being the unalloyed success that it should be.

After carrying on experiments with Carboloy, Widia, and Diamondite, over a period of two years, in three shops, the writer arrived at the decision that none of these cutting metals can be a success used as they are in present machinery. Even in some of our latest machine tools, they cannot be made to give 100 per cent efficiency, and it is not so much the fault of the material itself as it is of the machine tools, which were not designed to give that stability and power, with absence of vibration, that are so essential to the proper use of these metals to get their true worth in a machine shop.

This has also been true of Haynes' Stellite, and this alone has been the one thing that has caused Stellite to remain unadopted as a cutting metal by the world today.

The proprietors of these high-speed cutting alloys are carrying on a selling campaign that should not begin at the shops of the users, but should begin in their own laboratories. They should tabulate their results, showing the failures as well as the successes, then analyze the failures to find out the "why." A corrective suggestion will soon follow.

The proprietors should advertise their failures as well as their successes, so that the man in the shop will not attempt the impossible and as a result jump at a hasty conclusion, as is usually the case, and give the metals a bad name. Within the last two years, the writer has seen failure after failure and has heard of many more that would have been avoided had the proprietors of these cutting metals carried out the foregoing suggestion.

The tests and demonstrations so far carried on have been good in so far as showing the inherent qualities for usefulness in the metals, but tests must now be made to demonstrate the adaption of these stunts to actual production methods, then to demonstrate those methods instead of the stunts.

At the present time the builder of machine tools could stand a lot of education to produce a machine tool that could successfully use cemented tungsten carbide, and a let-up on the shops and proprietors of shops should be in order until it is definitely known what the actual capabilities of these metals are under present shop methods and with present shop tools.

It will be three or four years at the least before designers can possibly become acquainted with the capabilities and faults of these metals and even longer than that if the proprietors continue to stress selling above actual worth demonstration to the makers of machinery.

At the present time the writer can get far better results on cast iron from the old chilled cast-iron tools of my boyhood shop experience than from the new cutting alloys, and in many cases can get far better results with chilled cast-iron tools on good grey iron than can be obtained with high-speed tools, and high-speed tools beat the new cutting alloys on this metal when used on modern machines. When it comes to the hard white iron, all of the tools, excepting chilled cast iron, fell down.

Ernest F. DuBrul.[12] It is only two years since we first heard vague rumors about some mystery metal that gave wonderful results as a medium for cutting metal.

At the Cincinnati boat-ride meeting, the writer stated that such a cutting metal meant another revolution in designs of machine tools and that both builders and users of machine tools would do well to recognize the necessity of research on which to base new designs.

The writer pointed out that the introduction of a new and revolutionary cutting material was certain to proceed much faster than was the case with high-speed steel. There is greater

[11] Chief Engineer, Barker Machine & Tool Works, Green Bay, Wis. Mem. A.S.M.E.

[12] General Manager, National Machine Tool Builders Association, Cincinnati, Ohio. Assoc. A.S.M.E.

open-mindedness in industry at the present time; there is also more exchange of information between the different factors in the situation. It was pointed out that if this introduction were fast and furious, but without a basis of good research information, it would be extremely costly. The suggestion was made that a fund of $250,000 should be subscribed for definite, coordinated research to save great waste that would occur otherwise.

By December of the same year we had learned so much more about these materials that the writer raised the research ante from $250,000 to $500,000. It was then evident that we were facing precisely such a revolution as was caused by high-speed steel. It was pointed out that when Frederick W. Taylor made his experiments in cutting metals, which extended over a period of years, he had spent $250,000 in the course of those experiments. But a dollar in the first decade of this century had at least twice the purchasing power that a dollar has today. So that a fund of $500,000 nowadays could only be expected to duplicate in research about what Taylor had secured for the larger purchasing power of the $250,000 that he had expended.

In the last year and a half there have been much experimenting, much duplication, much expense, and much delay. Failures were duplicated, and successes were not always duplicated, nor were the successes always reported as fast as would have been the case if this work were coordinated.

The lack of coordination has caused much designing which will have to be done over after more facts are known. The writer feels more sure than ever in saying that the machine-tool industry will have wasted much money before this revolution in design is over and that this waste will amount to far more than the $500,000 fund suggested.

At the time this suggestion was made the writer also suggested, and he repeats it now, that the users of machine tools would find it to their interest to put up this research fund as quickly as possible. Eventually the user will pay for this waste, so it is to the users' interest to get the right results as quickly as possible, and without all the delays that are now being suffered due to lack of coordination of this research. Some of the problems of this revolution are entirely too large for any individual company to attempt to solve by individual research.

As evidence of the fact that much information is required, Mr. Digges says that the need of the sort of information contained in this paper is shown by the large number of inquiries received by the Bureau of Standards from users of machine tools. Mr. Digges' paper is a valuable contribution to the subject, but after all it is quite limited in its scope, due to limitations in time, funds, and various other factors. It merely gives the results of tests on one kind of material with a limited number of tools. One is not told what the results would be on other materials or with other types of cutting tools.

The manufacturers of tungsten-carbide tools have discovered that different forms of tool shanks produce quite different results. They do not yet know the best forms to use.

Up to the present time it is not known how high a speed and how heavy a cut the tungsten-carbide tools will stand. No one knows definitely what is needed in the machine tool to get the highest speed and best cut possible with tungsten-carbide tools. A year ago at Rochester the writer asked Mr. Bausch how fast a diamond will cut on brass. His answer was: "We don't know. We are cutting a thousand feet a minute, which is as fast as the machine will cut without setting up chattering that breaks the diamond." Today, a year later, it is not known how fast the diamond will cut.

Some builders of machine tools are presumptuous enough to say that their new machines are fully up to the limit of tungsten-carbide tools. They make this statement in their sales literature. This is a presumptuous statement, because they do not actually know what the limits of tungsten-carbide tools are. They might get a rude awakening some day when the real limits of tungsten-carbide tools are determined by scientific tests, unless they would find merely as a piece of luck that their machines are up to these limits. But from a cold-blooded basis of outright knowledge, any such statements today may turn out to be pure "bunk!"

Roger D. Prosser.[13] This paper covers the first really constructive piece of scientific investigation of a method of testing tungsten-carbide lathe tools, and developing equations showing the relations existing between cutting speed, feed, depth of cut, and tool life. It would certainly be interesting to see these tests carried further in a number of respects.

The size of the cemented-tungsten-carbide tip applied to the test tools has a very important bearing on the performance of the tools, and it would be very interesting to see the investigations extended to show a comparison of the performance between tools with various sizes of tips under the same cutting

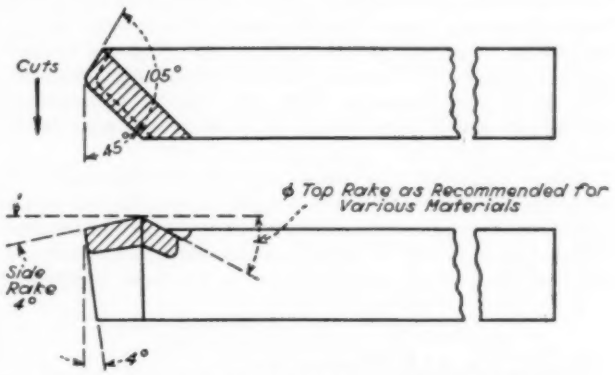

Fig. 13 Widia Tool, Krupp Shape for Heavy Work

conditions. The cost of cemented tungsten carbide necessitates its economical use, and such tests would indicate the minimum size of tip applicable for a given job.

Mr. Digges said that, with the copper brazed tools, it is necessary to remove the joint far enough away from the cutting edge so that it does not become dangerously hot during the operation. He also stated that premature failure in several tests resulted because of the rupture of this bond. Obviously, the tip of cemented tungsten carbide in this case was somewhat too small. A tip of sufficient size to carry away the heat would doubtless have overcome any difficulties in this respect.

In this connection, it has several times been stated that cemented-tungsten-carbide tools can be run with the cutting edges at a bright-red heat. Long experience and tests at the Krupp Works, where cemented tungsten carbide was originated, have shown that the best results are obtained when the speeds employed and size of tip are such that the heat is carried away and the cutting edge remains below a red color.

Mr. Digges stated that a small change in cutting speed causes a correspondingly large change in the tool life, so that the higher cutting speeds are obtained only at the expense of shorter tool life. In general, this is correct, but an interesting point is raised in that a higher cutting speed does not always result in a shorter tool life. In fact, when machining steel with cemented-tungsten-carbide tools, it is often possible to obtain satisfactory performance at a high speed, whereas with a slower speed the result is unsatisfactory. The writer has seen tests on machining

[13] Of Thomas Prosser & Son, New York, N. Y., American representatives of Fried. Krupp A. G., Essen, Germany.

electrode carbon when wear on the tool was actually less with a high speed than with a somewhat slower speed.

The statement is made by Mr. Digges that "if the curves are extrapolated to an extremely long tool life, then the curves will cross, and the high-speed-steel tools would show higher cutting speeds than the tungsten-carbide tools." This is of course theoretical, and it is quite doubtful whether this would be the result in actual practice. The writer believes, without having made investigations in this respect, that this result would not follow, but that for extremely long life the tungsten-carbide tools would still show a higher cutting speed than high-speed-steel tools.

The writer is in full agreement with the conclusions reached by Mr. Digges, and would especially call attention to his statements that, for a given area of cut, higher cutting speeds are obtained with deep cuts and fine feeds than with shallow cuts and coarse feeds; and also that high cutting speeds with relatively fine cuts are more favorable to successful application of tungsten-carbide tools then heavy cuts at slower speeds. The various manufacturers of cemented tungsten carbide have been trying to bring before the users of these tools the necessity for considering their limitations. Tungsten-carbide tools are not as strong as high-speed-steel tools, and therefore should be used with correspondingly lower chip pressures. This can best be accomplished through the use of high cutting speeds with somewhat lighter feeds than usual.

A few suggestions regarding practical considerations will doubtless be in order. It is felt that the form of the tool used in these tests, although a very good one, is not the best for tungsten carbide tools. In Fig. 13 is shown a tool which has been found, after exhaustive tests by Krupp, to be the most satisfactory

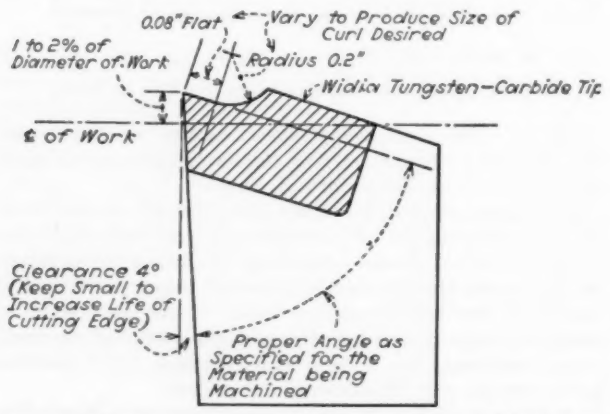

Fig. 14 Method of Grinding Chip Breaker in Widia Tool

for heavy roughing operations. The chip pressure on this form of tool is better distributed over the cutting edge than in the usual form of straight-side cutting tool. It also has other important advantages and is especially good for the machining of steel.

The clearance angle in the case of tungsten-carbide tools is of the utmost importance. It is noticed that Mr. Digges used tools with a clearance angle of 6 deg., and it would be very interesting if these tests were extended to show the relation of the clearance angle to the tool life. Clearance angles of 3 to 4 deg. have, in the majority of cases, resulted in greatly increased tool life, and some cases have been observed where a reduction of the clearance angle from 6 or 8 deg. down to 3 or 4 deg. has acutally doubled the life of the tools. Poor grinding is the cause of probably 80 per cent of all trouble experienced with tungsten-carbide tools, and it is of the utmost importance to observe carefully the grinding instructions of the manufacturers.

It is most important, when grinding a chip breaker on the top of the tool, not to weaken the cutting edge. Incorrect grinding of chip breakers is the cause of a large number of failures which have been encountered with tungsten-carbide tools. In Fig. 14 there is shown a satisfactory method of grinding a chip breaker, and it should be carefully noted that this is *not* accomplished by hollow-grinding the top of the tool; it is obtained by grinding a flat near the edge of the tool and parallel to the top surface of the tool. A small radius at the back of this flat produces very satisfactorily the proper form of chip, and the dimensions of the curl can be regulated by the width of the flat and the dimension of the radius. With this method the angle of the cutting edge can be made correct for the material being machined, and by this means the tool is not weakened, as in the case of hollow grinding.

Fig. 15 shows how hollow-grinding and the grinding of too great a clearance greatly weakens the tool.

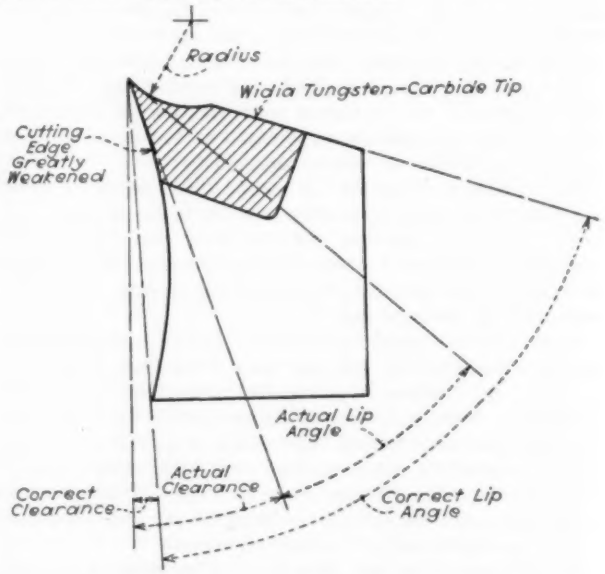

Fig. 15 Incorrect Grinding of Chip Breaker and Clearance in Widia Tool

It should be carefully borne in mind that the comparisons made by Mr. Digges between cemented-tungsten-carbide tools and high-speed-steel tools are applicable only to the grade of tungsten carbide used by him, and which contained about 13 per cent cobalt. With a harder grade, considerable higher cutting speeds would be obtained.

Mr. Digges points out that when the tool starts to become dull, the chips become shorter and shorter, with more and more curl, until they become very short indeed, rapidly breaking off from the work instead of coming off in clean-cut ribbons. It is most important for all users of tungsten-carbide tools when machining steel to note this point and to carefully instruct their men to remove tools from the machine for resharpening as soon as this condition begins to become apparent. Many failures of tungsten-carbide tools are due to allowing the tools to run after becoming dull, resulting in increased chip pressures and often bad breakages of the tools. This condition could be avoided by the observance of the form of chips and removal of the tool in time.

The investigations of Mr. Digges should be of the greatest value to all users of tungsten-carbide tools, and the writer wishes to compliment him on this contribution to the art of cutting metals.

Author's Closure

The author agrees fully with Mr. Williams that rigidity is essential for the maximum cutting efficiency with cemented-tungsten-carbide tools. However, this tool material can be and is being used to an advantage in a number of shops with the present machine-shop equipment. There is no doubt that in a number of cases a change in machine design is necessary in order to utilize the full cutting capacity of the new material.

It is very gratifying to have such close agreement between the conclusions made from the results of these experiments and those from actual shop practice as found by Mr. Prosser and his associates.

The author certainly appreciates the interesting discussions by Mr. Williams, Mr. DuBrul, and Mr. Prosser and hopes that additional results will be available for discussion at some future time.

MSP-52-14

Mechanical Lapping

By SYDNEY PLAYER,[1] WORCESTER, MASS.

IT IS A well-known principle of machine operation that ordinarily a machine can produce nothing more accurate than itself. However, by the use of modern lapping machines it is possible to produce work that is far more accurate than the machine being used.

The art of lapping is not new; it is so old it is impossible to determine its origin. With the ever-increasing demand for greater accuracy in mass production, particularly in the automotive industry, there arose an urgent need for some practical method of obtaining this accuracy easily, uniformly, and economically. It was common knowledge many years ago that the finest and most accurate surfaces produced on hardened steel were produced by the old method known to the trade as hand-lapping. This method was very slow and expensive, and could be performed only by the highest class of toolmaker. Hence it was used only when absolutely necessary. As a matter of fact, it is still used today in toolrooms where gages are made singly or where shapes of work are such that to lap by machine is not possible.

During the war there was developed by the Bureau of Standards, Washington, D. C., a method of mechanically lapping flat surfaces. This method, it is believed, is today known as the Hoke method. At the conclusion of the war it was adopted by the Pratt & Whitney Company, which, with the assistance of Major Hoke, developed and built what the author believes to be the first mechanical-lapping machines made in this country. However, these machines were for lapping flat surfaces only, and were used for lapping the Hoke size blocks, with which no doubt all are familiar. These machines, it is believed, are still in use and operating satisfactorily on this same work.

Early in 1922 the Bethel Player Company designed and marketed a cylindrical lapping machine, primarily for the production lapping of piston pins. This machine was a crude affair compared with the present-day machines. The production was small and the cost excessive, but the advantages gained far offset those items. Progress in the development of further machines naturally followed.

The year 1927 witnessed the development of new lines of improved lapping machines, both for the lapping of high precision work and for mass production where accuracy as well as rapid production is demanded.

A brief description of the machines at this point will no doubt help one to grasp the rapid strides the art has made.

Since this paper is devoted entirely to cylindrical and flat lapping, it will be confined to the description of machines for that purpose. There are two types of machines built, as follows:

(1) Vertical lapping machines for flat work (or cylindrical work) employing cast-iron plates for laps
(2) Vertical lapping machines employing a pair of abrasive lapping wheels.

Vertical Lapping Machine for Flat or Cylindrical Work

This machine is used primarily for precision cylindrical lapping, the work best suited being plug gages and other cylinders which require extremely close tolerances of accuracy. The machine has been designed along modern lines.

The lapping disks are made from a soft, close-grained cast iron. The lower lap revolves at a speed of 60 r.p.m. running counter-clockwise. The upper lap is stationary and free to float to find its own level, when brought in contact with a cage full of work to be lapped.

The lower lap is mounted on a tubular spindle driven by a hardened steel worm and bronze worm wheel, having a ratio of 10 to 1. Through this tubular spindle is a shaft running in bronze bushings and driven by a train of gears from the tubular spindle. This is called the "break-up shaft," for on its upper end is mounted a head with an adjustable slide carrying a drive pin. This drive pin is eccentric with the spindle an amount suitable to give sufficient movement to the workholder.

The workholder has a bushing in its center and is free to turn upon the eccentric drive pin. When the lower lap rotates, the work, being between the stationary and rotating lap, acts as a set of roller or ball bearings, carrying the workholder or cage around the eccentric drive pin at a speed of approximately one-half that of the rotating lap. The eccentric drive pin is driven in the same direction, but at a different rate, and the combination of movements due to the rotation of the workholder by a moving guide pin gives an ever-changing position of the work relative to the face of laps. This is what is meant by "break-up."

The vertical lapping machine, for lapping flat surfaces, is similar to the machine just described, with the exception of the workholder drive mechanism. It is used for precision flat lapping, such as gage blocks, etc.

The mechanism used for driving the workholder, or cage, is arranged to impart a motion to the work similar to that used by a toolmaker in hand-lapping. The lower lap again rotates on the tubular spindle by means of a worm and worm gear, the same ratio and speed being used.

Through the tubular spindle is mounted a stationary shaft, on the upper end of which is fastened a stationary gear. There is a head mounted, free to rotate upon the stationary spindle, and on this head are three vertical studs. On these three studs are the three workholder drive pinions in mesh with the stationary central gear; enveloping the three spider-drive pinions is a ring gear which is mounted on and driven by the tubular lap spindle. On the head of each spider-drive pinion a vertical drive stud eccentric with the pinion makes contact with a set of three bushings in the workholder. Upon rotation of the lap the ring gear imparts motion to the workholder drive pinions, these being mounted on a "sun and planet" train of gears. With the central gear stationary, the desired motion is given to the work. The ratio of the gears is chosen so that there is the same relative movement of the work with both stationary and rotating laps.

The workholder, or cage, used on these machines varies considerably from the simplest piece of sheet metal perforated with holes to the most complicated fixture. Its function is to hold the work in the proper relationship to the face of the laps and to impart the motion of the workholder drive studs previously referred to. The fixture most commonly used is what is known as a "leg spider," which consists essentially of a circular plate of aluminum, the edge or periphery of which is drilled and reamed with taper holes. These holes are not drilled radially, but are tangent to a circle approximately 3 in. in diameter drawn con-

[1] Norton Company.

Presented at a meeting of the Metropolitan Section, A.S.M.E., at Newark, N. J., March 20, 1930.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

centric with the center of the aluminum plate. In each hole is driven a spindle; this spindle is parallel and is about $^1/_{16}$ in. smaller in diameter than the hole in the cylinder to be lapped.

The cylinders to be lapped are assembled on these spindles on the workholder. They are free to revolve and have approximately $^1/_8$-in. end play. Outside the ends of the cylinders to be lapped and resting on four spindles which are longer than the rest, a ring is dropped retaining the cylinders on their respective spindles. Thrust plates are provided in the ring for each cylinder to rub against. This type of workholder lends itself to rapid loading and unloading, but two are usually provided for each machine so that there is no lost time in the machine when in operation. This type of workholder is lifted on and off the machine completely loaded.

A simple type of workholder, such as is used for flat work, consists of a circular steel plate suitably bushed for the drive studs, and arranged with holes or perforations to suit the work to be lapped. This type of workholder stays on the machine and is adjusted so that it touches neither lap, and the work is placed in the perforations while the holder is in position in the machine. These pieces are easy to load and unload; therefore, little time is wasted on this operation.

It is essential in all lapping operations that the laps be kept in good condition, both as to surface and form. The lap surfaces must be carefully prepared before commencing the lapping operation. The real secret of machine lapping is in having the lap surfaces in true plane. For very precise work the laps are hand-scraped from planing to a good surface plate. Three laps are taken and worked together, using as an abrasive nothing coarser than can be used for the lapping operation. For commerical work the scraping operation may be eliminated and a fast-cutting artificial abrasive, such as silicon carbide, used.

New laps are prepared by the following method before assembling on the lapping machine:

The working together is performed on an upright drill press, one lap being fastened to the table of drill press, the other lap resting on the top of it, the surfaces being prepared coming together with a film of abrasive and oil between them. From the spindle of the drill press extends a short throw crank. The crankpin of this crank is allowed to enter a driving hole in the center of the upper lap, this same upper lap being free to rotate and float freely about the crankpin. The drill press being set in slow motion, the upper lap is made to move in a circular path eccentric with the lower lap. This motion also makes the upper lap rotate slowly about its own axis, and the combination of these two motions has the effect of making the lapping faces of the pair of laps match each other.

The laps are made in the form of a heavy ring with the hole in the center greater than half the outside diameter. The thickness is usually 3 to 4 in. to prevent any distortion while in use. To obtain the true plane necessary these laps are taken, as previously mentioned, and by numbering them 1, 2, and 3 they are worked together in the following manner:

One with two, one with three, two with three, and so forth, as in the production of master surface plates. Having generated these true lapping surfaces, any subsequent dressing operation may be performed without removing them from the lapping machine, unless their form has been unduly destroyed.

This dressing operation is performed by releasing the overarm supporting the upper lap, allowing the upper lap to rest upon the lower with suitable abrasive, or lubricant, between the faces, and while the lower lap is rotated the upper one is moved back and forth a short distance by hand across the surface of the lower lap.

All is now ready to commence the lapping operation proper. Assume a number of steel cylinders 3 in. long, 1 in. in diameter, with a $^1/_2$-in. hole through them. The finished size is to be 1 in. plus 0.0001 in., minus 0.0001 in. The cylinders are finished ground to a limit of from plus 0.0002 in. to plus 0.0004 in. The finish of the grinding is not material, just as long as the diameters are within the foregoing limits. They are then loaded on the workholder and placed between the lapping plates.

A fine abrasive has been prepared, consisting of dust fines, aluminious oxide abrasives, mixed with kerosene and lard oil. The abrasive is then applied with a brush in small amounts and the machine is started. Between 30 and 40 cylinders are lapped at once. After running the machine for a few minutes, one is taken off and measured. Having been careful to take the time necessary to bring the first load down to size by giving all subsequent loads the same amount of time, and providing the grinding is between the limits specified above, load after load will be the same size, or easily within the limit of standard and plus 0.0001 in. The same procedure is followed for the lapping of flat disks, within these limits.

The average production on cylinders, removing the amount of stock specified, is about 60 to 70 per hour. A good commercial finish results.

For precision lapping to very close tolerances, two operations are required. For example, it will be assumed that there are being lapped 30 plug gages of a size 0.875 in. in diameter to limits of plus or minus 0.00002 in. To lap to this close tolerance, it is a better and quicker operation if the grinding is held to a closer limit than the commerical limit specified. Very good results have been obtained from a grinding limit of plus 0.00015 in. to plus 0.0003 in. In this case the laps used for both roughing and finishing must be prepared by hand scraping. Great care must be used in the dressing of these laps. In the case of roughing, the same abrasive is used to dress as that used to lap.

The author has found M-304 American Optical Emery a good rougher and fairly fast in its cutting action. This abrasive leaves a good surface for finishing.

The plug gages are lapped to within 0.00005 in. of finished size in this roughing operation. During the course of this operation, the work is transposed or rearranged in the workholder, usually by taking every alternate piece and placing it diametrically opposite. This means moving one-half the number of gages each time. By transposing, as just described, it will be readily seen that the larger diameters can be commingled with the smaller. By doing this three times during the course of the operation, one is assured of true parallelism and uniformity.

Having reached the stage for finishing, the gages are carefully washed without disturbing and placed in the finishing machine. The laps on the finishing machine have been hand-scraped, and then worked together with "levigated alumina" or "jewelers' rouge" until the surfaces of the laps are mirror finished. The operation is then continued without any further application of abrasive; a small amount of fine lubricant is used, however, to prevent the surfaces from drying. By continuing this method perfect mirror-like surfaces can be obtained, providing the material is suitably chosen and properly heat-treated.

For the complete lapping of these 30 gages to the foregoing limits, the time taken would be from two to three hours, the roughing only taking 30 min. Exactly the same procedure is followed for the lapping of precision size blocks.

Early in 1928 new types of production lapping machines were developed. These machines differ from the machines described previously in that they are very much heavier and abrasive bonded wheels are used for laps. Differing also from the previous machines, both abrasive wheels revolve in different directions.

For cylindrical lapping the top wheel runs 99 r.p.m., the bottom wheel 113 r.p.m. For flat work the same speed is used

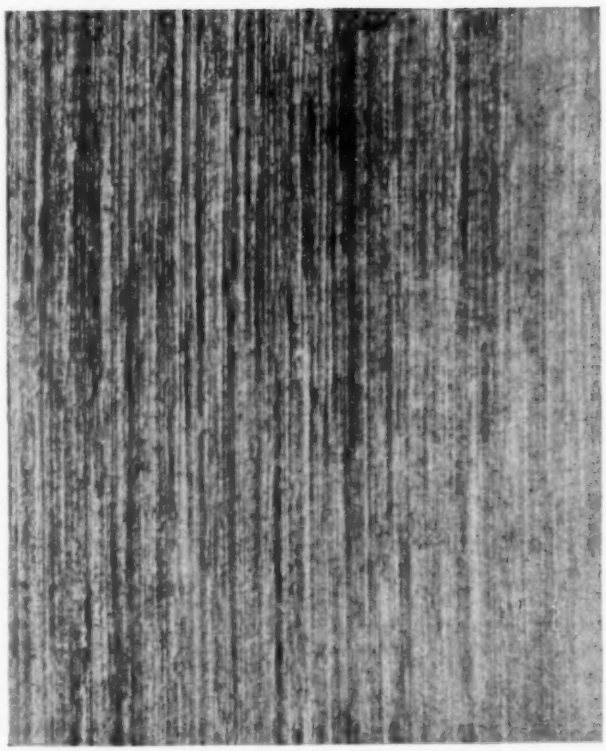

FIG. 1

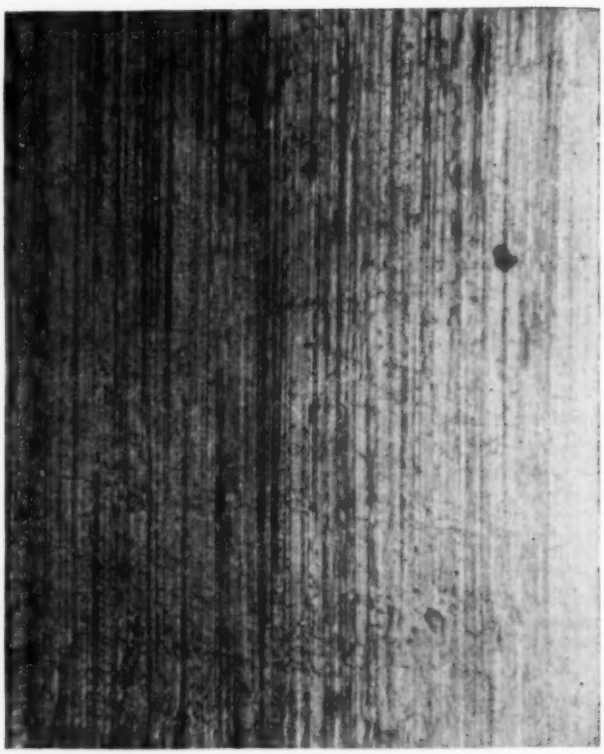

FIG. 2

FIG. 3

FIG. 4

for the bottom wheel, 113 r.p.m., but a little different speed is used on the top, 103 r.p.m. The upper wheel runs clockwise, and the lower wheel runs counter-clockwise. The reason on the cylindrical machine for the difference in speeds of the lapping wheels is to make the cage, or workholder, rotate about the eccentric drive pin, the combination movement thus given im-

parting what is known as a "break-up" to the work, relative to the lapping face of the wheel.

The "break-up" mechansim in both these machines is identically the same and needs no further description. The workholder, or cage, is the same.

For the dressing of the wheels a diamond dresser is provided, and both wheels can be dressed in true plane. The wheels preferably used are 24 in. in diameter by 3 in. thick, with a 14-in. hole. This gives the wheel a 5-in. face and enables one to lap work to that length.

The wheel problem presented great difficulty. However, we have succeeded in making wheels commercially, both for the rapid removal of stock and for the fine finish which is necessary for a lapped surface.

For rough lapping silicon-carbide abrasive or vitrified aluminum-oxide abrasive lapping wheels are used. For finishing, a very fine flour grain, silicon carbide, and shellac-bonded wheels are used with good results. Lubricant is pumped to the work and wheels from a large tank placed beside the machine, and consists of soap and water, lux being most commonly used.

Production on these machines is astounding, 500 piston pins per hour being easily maintained day after day, to limits of 0.0001 in. for straightness and roundness; stock removal for roughing, 0.0002 to 0.0004 in; for finishing, nothing to 0.0002 in. over high limit of finished piece.

Another big advantage gained in the use of bonded abrasive wheels is that no cleaning operation is necessary, as in the case where loose abrasive is employed.

This type of machine can also be used successfully in the lapping of soft metals, such as piston rings. By using these bonded abrasive wheels for laps it is claimed by engineers that no charging takes place, as is the case when lapping soft materials with cast-iron laps and loose abrasive. Several of these machines are in operation lapping the wristpins of airplane motors. These pins are comparatively soft, and when lapped by this method a bright mirror surface results. When using loose abrasive and cast-iron laps the finish is dull gray. While bonded abrasive wheels are used, this operation must not be confused with grinding as it is known today.

The face of the wheel is used and not the periphery. The results show no feed lines, no traverse marks, no corkscrew effect, but lines that are criss-crossed giving that velvety "matt surface" which shows the effect of genuine lapping. A high polish can be obtained by grinding machines by the use of fine-grained wheels and slow feeds, but upon close examination the grain marks run circumferentially and have ridges very much like fine threads.

A machine-lapped surface coming in contact with another moving part reduces friction to a minimum. It provides a more thorough and uniformly efficient distribution of the oil film surrounding it. Consequently, machine-lapped working parts, particularly those under great stress, will wear longer without reduction in size and there will be less risk of seizure, less noise, and longer life.

In the same way such parts as plug gages and gage blocks have a considerably longer life when lapped. This has been further substantiated by statistics compiled by several manufacturers who have made a study of gage life.

When machine-lapped parts are used in mass production, it is seldom necessary to have selective assembly. By this is meant that, with the very close limits to which machine lapping is held, it is not necessary to separate into groups of oversize or under limits, so that they may be chosen to fit a corresponding part that may be over or under size in itself, because of the wider tolerances of other methods of production.

Machine lapping eliminates all, or a great deal, of this selection of parts and its corresponding loss of production time.

Having described the machine and its operation, there will now be given some information concerning the cost of the operation and the almost unbelievable advantage of machine lapping over any other method of finishing a surface of hardened steel.

The author can do no better than quote from a paper[2] by L. M. McPharlin, supervisor of gages and inspection methods, Studebaker Corporation of America. Mr. McPharlin's paper states:

> The finish is most important and should be as smooth and uniform as it is possible to produce. We have found in our tests that the quality of finish governs to a greater extent than any other factor the wear life of plug gages; and when factors such as the steel, its treatment, and hardness are equal, finish is the deciding factor in the wear life.
>
> The experiments described were in progress for two and a half years and were necessarily slow in terminating, as the gages were used on production inspection and were carefully watched to avoid errors of any nature.

A comparison of accumulated wear of hand-lapped and mechanically lapped plug gages follows:

Both gages plugged 6000 holes; the hand-lapped gage lost 0.00065 in. end, 0.00028 in. center, and 0.00012 in. back. The mechanically lapped gage lost in size 0.0002 in. end, 0.00002 in. center, nothing back. The two gages differed only in surface finish. They were both of the same size, made of the same kind of steel, hardened to 87 scleroscope, and were the same material. The mechanically lapped surface showed 454 per cent more life then the hand-lapped surface.

This paper by Mr. McPharlin is a very interesting one and is well worth reading.

Further data have been obtained on lapping in massed production form. One of the large automobile plants is using 35 centerless grinding machines for grinding wristpins, leaving 0.0003 in. for lapping on vertical lapping machines employing abrasive lapping wheels. Four machines are used for rough lapping and four for finishing. These eight machines lap around 10,000 pins in 19 hours, or better than 500 pins per hour.

To illustrate this, the series of microphotographs of wristpins herewith show the surfaces magnified 300 times. The pins shown are the same in all photographs.

Fig. 1 shows a good commercial centerless ground finish.

Fig. 2 shows what is called a centerless lapped finish.

Fig. 3 shows a rough lapping operation performed on a vertical lapping machine after the operation of centerless lapping.

Fig. 4 shows a finish-lapped pin done on a vertical lapping machine following the rough lapping. It is not necessary to comment on the difference in surfaces shown; the finish surface mechanically lapped on a vertical lapping machine being far superior to the one finished on a centerless grinder and the one described and shown as centerless lapped. The one described as centerless lapping appears good to the eye, is highly polished, but underneath the polished surface all the evidence of the grinding wheel may be found, and after pushing through a bushing the high spots will be noted. Experience has shown that this pin will lose its size rapidly until all the high spots are rubbed down to make what is known as a "worn surface." The surface from a vertical lapping machine needs no further running in, the high spots being lapped to a matt finish.

In the author's early experience a test was made at one of the large automobile factories, running an engine several hours with ground pins versus lapped ones. After several hours of running the engines were dismantled and the pins were measured. The ground pins had lost in size 0.0003 in., and the lapped pins showed no measurable difference in size.

Tungsten-Carbide Cutting Materials

Progress Report No. 2[1] of Subcommittee on Tungsten-Carbide Cutting Materials of the A.S.M.E. Special Research Committee on the Cutting of Metals

By FRANK C. SPENCER,[2] KEARNY, N. J.

WITH THE assistance of the National Machine Tool Builders' Association, this subcommittee has sent out letters and questionnaires to over six hundred users and builders of machine tools requesting certain specific information based on their experiences with the use of tungsten carbide as a cutting material. It was thought that the analysis of a large amount of data obtained in this manner would bring to light such deficiencies as might exist in the tools and in the machines which, if corrected, would make it possible to obtain the maximum advantage from the use of this material. Copies of the letter and questionnaire are included as a part of this report.

About seventy-five concerns had replied at the time this report was prepared, of which about fifty furnished data on most of the items covered by the questionnaire. The others were making tests but had no information available, or had not used tungsten carbide at all. Replies are being received daily, and it is hoped that sufficient information will be obtained to warrant the preparation of a more complete report later. The following is a digest of about fifty replies presenting experiences with the use of tungsten-carbide tools and comments of users bearing upon the design of machine tools.

A—Extent of Application

The returns show that a relatively small average number of machining operations are now being regularly performed using tungsten-carbide tools, although in two companies the number of applications is over 500 in each. Probably a better indication of the extent of application is the low percentage of the number of tungsten-carbide tools to the total number of tools available. This percentage is considerably less than one per cent; but there are, however, several notable exceptions—one machine-tool builder reports 5 per cent, one 15 per cent, and another 25 per cent. One company is using tungsten-carbide tools for 75 per cent of all cast-iron turning.

While the total volume of production now being obtained with the use of tungsten-carbide tools is still relatively small, the replies indicate that practically all of the companies reporting have definite programs planned which contemplate the more extensive use of tungsten carbide, provided that "tests which are now being conducted prove to be satisfactory."

One company is planning to equip 1000 machines with tungsten-carbide tools for the general machining of metals, and another is conducting a test which, if it "shows that a saving can be effected, plans to use them exclusively on all cast-iron, semi-steel, bronze, and brass machining," with the possibility of extending the application for machining 1000 different parts.

B—Kind of Material Cut

Experiences indicate that tungsten carbide is superior to tool or high-speed steel as a cutting material on all non-ferrous metals regardless of the hardness or the condition of the surface, especially for roughing cuts on production jobs. Not all are agreed, however, that finishing can be done as satisfactorily as with high-carbon- or high-speed-steel tools, because "tungsten carbide is comparatively weak and brittle," and "will not hold a fine, keen edge."

Cast iron submits readily to the tungsten-carbide tools even when the surface has a hard sandy scale. One company reports, "We have to cut through chaplets and welds where blowholes have been acetylene welded. Tungsten carbide does not seem to fail in cutting through these defects." Others report similar experiences.

A difference of opinion exists as to the advantage of using tungsten-carbide tools in machining steel. Several report failures in attempts to improve on high-speed-steel performance, while others are enthusiastic about the use of tungsten carbide for machining steel and report having readily machined alloy steels which could not be machined economically with high-speed steel. One company reports machining a hand-forged nickel-chromium steel airplane propeller shaft. It is stated: "It was extremely tough and irregular in shape, necessitating in frequent instances materially heavier cuts on one side than on the other. Scale conditions and hard spots were particularly difficult." The shaft was turned on a Gisholt turret lathe about 10 years old but in good condition. "The job was successfully completed using tungsten-carbide tools—as we found it absolutely impossible to finish the machining of the parts using high-speed-steel tools without first annealing the forgings, and then only with great difficulty."

C—Machine Equipment Used

Machines on which tungsten-carbide tools have been used successfully on regular production include practically all standard types of metal-cutting machines, except milling and drilling machines which, replies indicate, have been equipped with tungsten-carbide tools for use principally on an experimental basis.

The machines on which tests were made or on which regular operations were being performed in most cases were reported in good condition. Two reported as follows: "Condition varies from good to poor, much more satisfactory results being obtained from machines in good condition." An electric company, in

---

[1] This report was presented at the Machine Shop Practice Session of the A.S.M.E. Semi-Annual Meeting in Detroit, Mich., June 9, 1930.

[2] Assistant Superintendent, Manufacturing Development, Western Electric Co. Mem. A.S.M.E. Mr. Spencer was employed as a draftsman in the Ordnance Department at Washington during 1902 and 1903, and in 1904 was appointed chief draftsman at the Springfield Armory, Springfield, Mass. In 1918 he held the position of superintendent of the Browning Gun Department at the Colt's Patent Fire Arms Manufacturing Company at Hartford, Conn., but during most of the time since 1906 he has been employed by the Western Electric Company in various capacities, starting as machine designer at the Chicago plant. In 1923 he was placed in charge of the machine-design division at Hawthorne and in 1925 was appointed assistant superintendent in charge of manufacturing development. During the last couple of years he has been engaged principally in the procurement of machine equipment for the new plants of the Western Electric Company.

referring to its equipment, stated, "Generally one will find the equipment in fair condition and about 5 to 10 years old. Tungsten carbide can be used advantageously on machines of this age provided the proper selection of the tool is made."

D—Tungsten-Carbide Tools Used

Practically all of the tools used by the companies reporting were lathe- or planer-type tools in a large variety of shapes and sizes, some having shanks as large as 2 in. × 2½ in. Tips in most cases were simply brazed, though a few were inserted, and in one or two cases they were dovetailed and brazed. The rake and clearance angles in most cases were those recommended by the suppliers, but in some instances customers found modifications of these angles desirable on certain kinds of work. This subject is sufficiently important to warrant further consideration, and it will probably constitute one of the Commitee's future activities.

E—Grinding of Tungsten-Carbide Tools

As reported above, lathe and planer tools constituted a large majority of the tungsten-carbide tools reported upon, and the grinding was done mostly by hand. Eight out of thirty companies reported using cutter-grinder machines also. A few of the companies have the grinding done by the suppliers One company reports grinding "not essentially different from standard tool-dressing methods;" another, "Tools were ground in our tool room by one man, who was instructed as to proper methods."

A gear company cutting cast iron, brass, and bronze castings reported that the time consumed in grinding is from one to three hours, according to the condition of the tool. Another stated that the time required is twice that for grinding high-speed-steel tools, while another, machining bronze, reports three to five minutes as the average time required.

A company machining "nearly all commonly used materials" reported that "considerable time was spent in sharpening tools, and we found it difficult to maintain a keen edge for any length of time." Another shop doing very heavy work stated that "after original grinding, only a few minutes each day is required for occasionally touching up the cutting edge." A company machining aluminum alloys reports the time for grinding is negligible, and another reports the time consumed about 5 times that of high-speed-steel grinding.

Apparently the practice of grinding tungsten-carbide tools differs as greatly as the grinding of tool-steel and high-speed-steel tools. The importance of maintaining the correct rake and clearance angles on tools used for production work which can only be accomplished by machine grinding, seems to be generally disregarded. The subject of small-tool grinding warrants further investigation.

F—Method of Lapping

Of 40 companies, 11 reported the use of tungsten-carbide tools lapped or stoned. The lapping has been done mostly by hand, using a cast-iron lap, though in a few cases disk lapping machines are used, silicon carbide or diamond dust with oil being used as an abrasive. The advantage of lapping tungsten-carbide tools is questionable.

G—Cutting Speeds Used in Feet per Minute as Compared With Cutting Speeds of Tools Previously Used

The increases in cutting speeds using tungsten-carbide tools in cutting cast iron and non-ferrous metals have been from two to three times the cutting speeds using high-speed-steel tools. Many are using the highest speed that the machines will permit. One report stated relative to cutting bronze, "We have made several tests of cutting speeds and have got as high as 400 ft. per min., but could not maintain this due to the construction of our machine tools." Another reported: "In a few cases where we originally tried to get full speed and feed capacity of the tool, the strain on and chatter of the machines was so great that we had to cut the speed down, and we are now only increasing speeds gradually as operators get familiar with the tool possibilities."

H—Feeds Used in Inches per Revolution or Stroke as Compared With Feeds on Tools Previously Used. I—Depth of Cut in Inches

The general practice seems to be to use about the same feeds and depth of cut in cutting with tungsten-carbide tools as with high-speed-steel tools. No radical differences have been reported. A tendency is indicated, however, toward lighter feeds, with much higher cutting speeds than are used with steel tools.

J—Economies in Percentage of Increased Output as Compared With High-Speed Steel and Stellite

Some remarkable increases in outputs per grind using tungsten-carbide tools for machining cast iron and non-ferrous metals have been reported, as compared with high-speed-steel tools. These increases appear even more remarkable when we consider that the cutting speeds used as already noted were in most cases from two to three times former speeds using high-speed-steel tools.

A company machining silicon-aluminum alloys reports that with the use of tungsten-carbide tools they obtained 4500 to 35,000 pieces per grind, whereas with the use of high-speed-steel tools they obtained 100 to 1800 pieces per grind. An airplane company in turning aluminum bronze obtained 2000 pieces per grind using tungsten carbide, against 60 pieces per grind using high-speed steel, and in boring aluminum-alloy crankcases having 8 bearings each, 50 to 75 crankcases per grind using tungsten carbide, against one using high-speed steel. Another airplane company stated that they could not report on the output of some of their tungsten-carbide tools because of the fact that the set-ups have not been disturbed since the tools were first put to work more than six months ago.

A company machining cast iron reported 1500 pieces per grind using tungsten carbide as against 100 using high-speed steel. They also reported that in grinding they do not remove more than 0.003 in. to 0.005 in. from the tungsten-carbide tool, whereas up to 1/32 in. is ground away each time the high-speed-steel tool or stellite tool is ground. Another company machining cast iron reports the number of pieces per grind using tungsten carbide is 1500 per cent over the number using high-speed steel, and the increase in the number of grinds in the life of the tool "due to the small amount removed in grinding would be about 200 per cent."

A valve company machining non-ferrous metals reported as follows: "As compared with high-speed steel, one particular job shows an increase of approximately 2400 per cent in pieces per grind and an increase of approximately 560 per cent in the number of grinds per tool. On another operation where tungsten-carbide tools replaced high-speed steel, the number of pieces per grind increased something like 1600 per cent."

Practically no information was furnished relative to a comparison of tungsten-carbide tools with stellite tools with respect to the output per grind.

Longer runs without the necessity of shutting down for tool grinding result in an appreciable increase in machining production efficiency, without the necessity for spectacular increases in cutting speeds. Large economies are effected with the use of tungsten carbide on such operations, even when used on equipment that was not designed for the severe service tungsten carbide will withstand.

Considering the gain in production resulting from long, uninterrupted runs combined with the gain resulting from the high

cutting speeds obtainable with this material, the possibilities of cost reduction are considerable.

K—Failures

A few companies reported no failures whatever, although most of the companies including those which have been able to effect satisfactory savings using tungsten-carbide tools have had several discouraging experiences—some due to unsatisfactory tools, some to machine deficiencies, and some no doubt to unfamiliarity with the technique involved in the use of the material.

With respect to tool troubles, one large company stated: "We have had set-ups which gave us considerable trouble, and which finally worked out only after a new set of tools was installed by changing suppliers. We believe that tungsten carbide is very inconsistent in hardness and grain structure, and that the tipping is not always satisfactory, which generally causes failure of a set-up." Another stated: "Our failures have been under heavy cuts which caused the shank of the tool directly under the cutting edge of the tungsten-carbide bit to compress and mushroom out, causing the tip to break due to improper support."

One large company's report summed up the statements of several: "Have had the usual failures experienced by others, such as those due to tools having too great overhang, to making intermittent cuts, to operator stopping machines and starting again with feed on, to operator running machine in reverse accidentally, to not exercising care when tool leaves the work, and when blowholes are encountered."

Quoting from reports of other companies: (1) "We could only increase speed a little before we reached the maximum speed of machine, and when we attempted to increase the feed, the tips came off." (2) "The only failures we have had were when the tool had to be stopped in the cut. Sudden shocks break tungsten-carbide tools." (3) "Set-up called for three roughing tools at one time. It was necessary to remove one tool for lack of power after the belt and clutch were tightened as much as possible without injury to the machine." (4) "On the full-automatic lathe, the tools were used in conjunction with a follow rest and the work was driven by means of serrated dogs. Any slight slipping of the work or misalignment of it while being inserted or ejected from between centers chipped the cutting edge, and it seemed almost impossible to get a full run from a tool." (5) "The machining of malleable-iron and brass wedge gate-valve disks has been unsuccessful owing to considerable vibration when running at the proper speed. Although the floor under the machine was strengthened and an entirely new machine installed, considerable vibration still existed and resulted in chatter." (6) "Tried tungsten-carbide tools and found that the first requirement of their successful use is rigidity of the machine tool. Since we have practically no machines in our plant rigid enough for the use of these tools, we abandoned further experiments."

A condition reported by two companies regarding the wear of the front face of the tool, thus reducing the clearance angle, is stated by one of them as follows: "Had no particular success on tough steels. There seemed to be a pressure on the nose of the tool which resulted in an abrasive action which rapidly wore away the front clearance."

Another unsatisfactory condition reported by three companies was the wearing of a groove on the top of the tool directly back of the cutting edge. One of the companies stated that this occurred when machining nickel-chromium-steel forgings and caused the cutting edge to break. This difficulty was obviated by grinding a groove at the point where it wore, thus reducing the compression of the chip as it was being cut from the work, and consequently reducing its pressure on the top of the tool.

L—Suggestion for Design Changes of Machinery to Make Possible the Most Efficient Use of Tungsten-Carbide Tools

Practically all of the experiences reported indicate that this material possesses possibilities for the improvement of machining practices far beyond those already attained, provided further improvement is made in the material and in the tools and machines to withstand the more severe service to which they will be subjected. There is still much to be done, especially in the design of machines, and a consideration of some of the suggestions which have been submitted for their improvement would not be amiss. The suggestions are as follows:

1 Utmost rigidity of the frame, driving shaft and spindle, tail stocks, or other members subject to strain is essential in order that deflections shall be extremely small.

2 Large-capacity ball bearings, preferably preloaded, or adjustable roller bearings of precision quality, should be used for spindles to withstand heavy loads and to eliminate bearing clearances or reduce them to a minimum.

3 Considerably higher speeds are obviously necessary.

4 Greater power should be provided, with a large allowance for overload so that machine will not stall when cutting.

5 It is important that feeding mechanisms be designed to eliminate jumping due to the building up and sudden release of pressure on tools.

6 Tool holders should be heavier and designed to eliminate the overhang of tools, and the method of clamping tools in holders should be improved to insure rigidity.

7 Better provision should be made for handling chips and for protecting operators from flying chips.

M—Any Additional Information That Is Available, Such as the Attitude of Labor With Respect to This Material, the Difficulty of Training Operators in the Use of It, Difficulty of Tipping Tools, and the Like, Would Be of Value

The replies received contain much valuable information and many terse comments pertinent to the subject of tungsten-carbide applications, and this report would be incomplete without the inclusion of some of them. The following are typical:

1 "After the operators become familiar with the possibilities of tungsten-carbide tools, they are reluctant to go back again to high-speed steel."

2 "We have been conducting a lot of tests, some successful and some not. We started out using just one or two tools on different machines, obtaining various results. We finally completely equipped one 24-in. Bullard turret machine with a set of 13 tools which covered practically all of the work which we were doing on this type of machine. This was at a cost of $652 as against a cost of $43 for high-speed tools of the same size and number. We have kept comparative costs as against high-speed steel, and find that our savings average approximately 31 per cent in time over that of high-speed steel."

3 "Tungsten-carbide tools have not progressed beyond experimental stages, though we have been working with the material ever since its introduction. We have not found it satisfactory as a cutting medium in our production work, where we are called upon to machine high-carbon chrome-steel forgings of an analysis similar to S.A.E. 52,100 annealed to a Brinell hardness of 170. In all trials of tungsten-carbide tools on this material it has proved less satisfactory than cobalt high-speed steels.

"We have found tungsten-carbide tools exceedingly satisfactory on cast iron, where we have been able to take very increased depths of cut at higher cutting speeds.

"We note an interesting condition in the use of tungsten-carbide tools on either high-carbon chrome or low-carbon steels:

namely, that if we introduced the tool into the work carefully, a continuous cut could be taken at high surface speed and corresponding coarse feed, without any detriment to the tool so long as the tool was not removed from the cut; but when the tool was removed, a small piece of the cutting edge remained in the work. This was demonstrated any number of times, and so far we have found no way of overcoming this difficulty.

"In general, we believe that standard machines made within the last three or four years are sufficiently powerful and have the necessary speed range to use tungsten carbide on work to which it is adapted. We have every confidence in the possibility for increased production and savings in the cost of machine operations by the careful application of this material."

4 "Generally speaking, we have found it impractical to adopt tungsten carbide as a cutting material for general use in our shop. While greatly increased speeds and feeds are possible on certain jobs, the overall saving on most of our work does not justify the high cost and frequent breakage of the tools. The reason for this condition is that the actual cutting time is not a very large part of the total time, because we subdivide cuts wherever possible and because our quantities are not very large. We also have to machine parts which are too frail to stand any more speed or feed than is obtainable with a high-speed-steel tool.

On the other hand, we have found tungsten carbide to be very useful in cases where we have had to machine hard or abrasive materials such as chilled cast iron, hardened steel, very hard bronze, sandy steel castings, or other materials which high-speed-steel tools would not cut at ordinary speeds. In such cases the time saved seems to justify the high cost of the tools. For the machining of soft materials such as cold-rolled steel and gray cast iron in small or medium-sized quantities, the present cost of tungsten carbide seems entirely too high to make it commercially practical."

Conclusion

Tungsten-carbide tools have been on the market for about a year and a half, but their use on production work is very limited as yet. A year ago it was thought that the development of tungsten carbide with respect to material and tools would progress much more rapidly than improvements would be made in adapting machines to the use of this material. This does not seem to have been the case. Improvements in the quality of the material, and in the efficiency of the tools and machines, seem to be advancing together. The improvement of the machines, however, is a large undertaking, and we may expect important changes in design for some time to come. A large amount of evidence proves that for certain classes of work, tungsten-carbide tools can be used with considerable economy on old-style machines provided they are in good condition. These tools are being experimented with by a large number of machine-tool users in an endeavor to adapt them to present machine set-ups. We need not expect that the transition from the use of old-style machine equipment to the use of highly developed machine equipment due to the more general adoption of tungsten-carbide tools will be unduly rapid.

The technique involved in the use of tungsten-carbide tools is quite different from that involved in the use of steel tools, and it will take some time to train shop people in the proper methods of handling, grinding, and setting up tools and machines. The development of this technique is rather expensive, but if the initial applications are made where appreciable saving can be effected, the cost of further and more difficult applications will be compensated for, at least to some extent. A wide demand for machine equipment from which maximum efficiencies can be obtained with the use of tungsten-carbide tools will undoubtedly develop with experience gained from applications on present equipment.

The Subcommittee extends thanks to the National Machine Tool Builders' Association for assistance rendered in the distribution of letters and questionnaires, and also to the many companies who responded for their well-prepared replies.

LETTER ACCOMPANYING QUESTIONNAIRE

Dear Sir:

A subcommittee on Tungsten Carbide Cutting Materials was authorized at the December, 1929, meeting of the A.S.M.E. Special Research Committee, and has since been organized. The members are as follows:

Prof. O. W. Boston, University of Michigan
W. A. Wissler, Union Carbide & Carbon Research Lab.
Coleman Sellers, 3rd, Wm. Sellers & Company
A. H. Bainton, Brown & Sharpe Mfg. Co.
Roger D. Prosser, Thomas Prosser & Son
G. N. Sieger, Carboloy Company
M. E. Lange, Warner & Swasey Company
T. G. Digges, Bureau of Standards
F. C. Spencer, *Chairman*, Western Electric Co., Inc.

The purpose of this Subcommittee is to correlate the research activities of various organizations, firms, and individuals with respect to tungsten carbide as a cutting material, and to investigate and report on the needs of the machine-tool industry in the matter of machine design as affected by the use of this new cutting material. To this end it is necessary that the Subcommittee consult with the metal-cutting industries and machine-tool builders in order that such information as is available may be correlated and disseminated in such a manner as to be of greatest value to these industries.

The Subcommittee would like to present a compilation of the obtainable data on the use of tungsten carbide tools at the Spring Meeting of A.S.M.E., which is to be held at Detroit in June, and solicits your aid in the preparation of such a report. If you will kindly have the engineer in charge of the introduction of tungsten carbide in your plant prepare a report covering a few typical examples of your experiences with this material, following the questionnaire attached the Subcommittee feels that you will be more than repaid for the trouble by receiving the combined report of a large number of experiences of other users. The compilation of this information will be expedited if the reply to each one of the lettered questions is made on a separate sheet. It is fully appreciated that it may be difficult to furnish information on every item. Please furnish, therefore, whatever information you have available. This should be received by May 1, 1930. After that date, the Committee would be glad to receive any further information you may obtain. The names of the concerns furnishing this information will not be published.

Kindly address communications to the Subcommittee on Tungsten Carbide Cutting Materials, A.S.M.E., 29 West 39th Street, New York, N. Y.

Subcommittee on Tungsten Carbide Cutting Materials,
F. C. Spencer, *Chairman*.

QUESTIONNAIRE COVERING THE USE OF TUNGSTEN CARBIDE AS A CUTTING MATERIAL

A—Extent of Application
- 1 Approximate number of operations on which used
- 2 Approximate percentage of tungsten carbide tools used to total tool equipment
- 3 Contemplated uses
  - *a* Nature of
  - *b* Number of.

B—Kind of Material Cut
- 1 Analysis
  - *a* Composition
  - *b* Heat treatment
  - *c* Condition of surface scale
  - *d* Physical characteristics.

C—Machine Equipment Used
- 1 Type
- 2 Conditon
  - *a* Good
  - *b* Fair
  - *c* Poor.

D—Tungsten Carbide Tools Used
- 1 Description
- 2 Method of tipping
  - *a* Dovetail

b Brazed
c Inserted
3 Size of tool shank
4 Shape of nose
5 Cutting angles
a Front and side rake
b Clearance angles
6 Limitations
a Used for a specific job
b Used for several jobs.

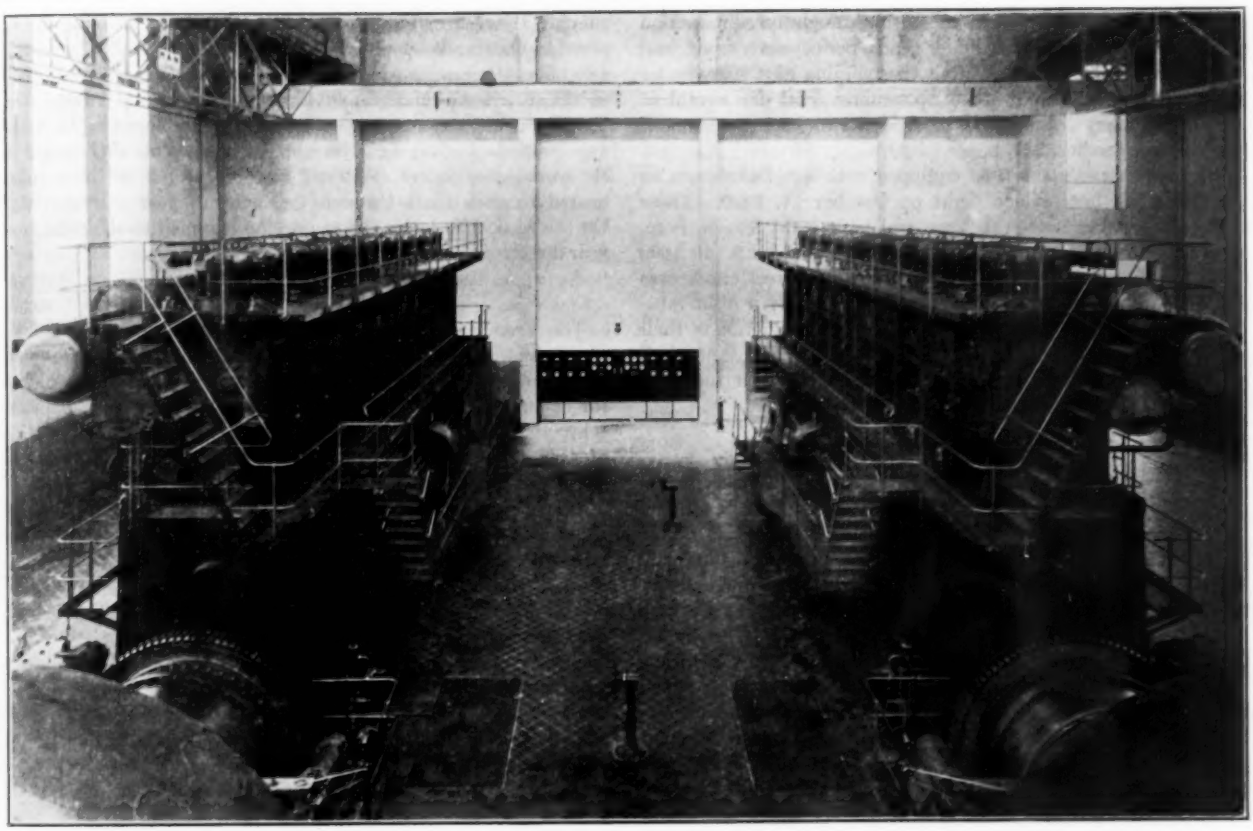
E—Grinding of Tungsten Carbide Tools
1 Method
2 Type of wheel used
3 Time consumed for grinding.

F—Method of Lapping Tools, if Done

G—Cutting Speeds Used in Feet Per Minute as Compared With Cutting Speeds of Tools Previously Used

H—Feeds Used in Inches Per Revolution or Stroke as Compared With Feeds on Tools Previously Used

I—Depth of Cut in Inches



J—Economies in Percentage of Increased Output as Compared With
1 High-speed steel
a Number of pieces per grind
b Number of grinds in the life of the tool
2 Stellite
a Number of pieces per grind
b Number of grinds in the life of the tool.

K—Failures
1 Description of machine set-ups which failed
2 Corrective measures tried.

L—Suggestion for Design Changes of Machinery to Make Possible the Most Efficient Use of Tungsten Carbide Tools

M—Any Additional Information That Is Available, Such as the Attitude of Labor With Respect to This Material, the Difficulty of Training Operators in the Use of It, Difficulty of Tipping Tools and the Like Could Be of Value.

(Prepared by Subcommittee on Tungsten Carbide Cutting Materials and circulated with preceding letter.)

24,000-Hp. Peak-Load M.A.N. Oil-Engine Plant at Henningsdorf, Near Berlin, Germany

Progress in Oil- and Gas-Power Engineering*

Contributed by the Oil and Gas Power Division

Executive Committee: E. J. Kates, *Chairman*, L. H. Morrison, *Secretary*, H. A. Pratt, Harte Cooke, and L. M. Goldsmith

RECENT oil-engine developments have been revolutionary—during the last year oil engines of two widely different designs "went up in the air" in airplanes; a large British airship propelled with oil engines has just been commissioned; a 24,000-hp. stand-by and peak-load stationary power plant was recently started; a battleship with 50,000-s.hp. propelling plant has been laid down; and for the 100,000-hp. power plant of the new electrically propelled White Star liner, oil engines are being seriously considered. The principal reason for much of the progress has been the development of means to materially reduce weight and space requirements of oil engines and thus make them lighter and cheaper, thereby widening their field of application. Higher piston and rotative speeds, airless injection of fuel, supercharging of four-cycle engines, double-acting cylinder construction, special types of frame construction, improved materials—all of these have contributed to each individual success.

Aircraft Oil Engines

The Attendu experimental two-cylinder two-cycle engine,[3] built some time ago for the Navy Department in the hope of developing it for airship propulsion, gave disappointing results as to fuel consumption and thereby forfeited one of the expected advantages in large cruising radius—yet the new Packard airplane engine was the indirect result of this experiment. This engine, which first flew on September 19, 1928, later made the epochal 650-mile trip from Detroit to Langley Field on May 13, 1929, at a fuel cost for the trip of $4.68 instead of $25 for gasoline. This radial 9-cylinder engine develops 200 hp. at 2000 r.p.m. and weighs less than 3 lb. per b.hp.[1] A single automatic combination inlet-exhaust valve is fitted in each cylinder crown, and the propeller airstream is relied on to blow away the exhaust gases which the pistons force out and fill the cylinder on the suction stroke. A small single-plunger fuel pump is mounted ahead of each cylinder with a short pipe to the single injection valve. A special factory has been built by the Packard Company for the economical manufacture of these engines on a production basis. Henry Ford has also taken up experimenting with an oil engine for airplanes.

Last February in Germany another oil engine made several successful flights. Professor Junkers[2] modified his well-known opposed-piston construction to use two separate crankshafts

* Numbered references in the text relate to the Bibliography at the end of the report.

with the air propeller driven by both through 1:1.4 reduction gearing. Here the lack of cylinder heads, perfect scavenging, and equally perfect balance permitted the building of a six-cylinder 700-hp. engine running at 1600 r.p.m. on a total dry weight of 1780 lb. or about 2½ lb. per hp., while its fuel consumption on test is claimed to be 0.3971b. per b.hp-hr.

The British airship *R-101*,[3] equipped with five Beardmore oil engines, made her maiden flight on October 14, 1929. These engines are of the four-cycle type and have eight 8¼-in. bore, 12-in. stroke cylinders designed to develop 650 b.hp. at 1000 r.p.m., while their weight is 4600 lb. with cast-steel crankcases and 3600 lb. with aluminum ones. Unfortunately, considerable trouble from torsional vibration has forced the reduction of their rated speed—and therefore horsepower—and increased their unit weight. Airless fuel injection is used, and their fuel consumption is claimed to be 0.385 lb. per b.hp-hr.

Marine Oil Engines

The year marked the completion of the second Dieselization program of the U. S. Shipping Board, so that now a total of twenty-three single-screw vessels constitute the nucleus of the motorized American merchant marine. Eleven ships are equipped with double-acting engines, of which four are Worthington two-cycle four-cylinder units, four more are powered with M.A.N.-type two-cycle four-cylinder engines, and the remaining three are of the McIntosh & Seymour four-cycle type, one four-cylinder and two five-cylinder units. Of the nine ships equipped with single-acting engines, six have Busch-Sulzer two-cycle six-cylinder engines, while three others have McIntosh & Seymour four-cycle six-cylinder engines.

The three remaining conversions finished during the year are electric-drive ships with four trunk-piston McIntosh & Seymour engines driving electric generators, and a single propelling motor of 4000 s.hp. at 60 r.p.m. The engines are of the single-acting four-cycle type, rated to develop 1280 b.hp. at 250 r.p.m. in eight cylinders of 20 in. bore and 24 in. stroke.

Private enterprise in the United States has been responsible for only one larger motorship—a freight and passenger ship for the American and South African Line in which two 2700-s.hp., 95-r.p.m., four-cylinder, Sun Doxford two-cycle, opposed-piston engines of 21.26 in. bore and 85.04 in. combined stroke constitute the propelling plant.

Foreign Marine Oil Engines

The rest of the world has appreciated the advantages of the marine oil engine to a much larger degree—not less than twenty-seven motor passenger liners of over 10,000 tons were reported under construction in Europe and Japan last July. Of these, 13 are to be propelled by single-acting two-cycle engines and 3 by double-acting two-cycle, 10 will have double-acting four-cycle machinery, while only one will have an engine of the single-acting four-cycle type. Out of all the merchant vessels under construction, about 1,400,000 tons or 49.5 per cent are motorships,[4] with 1,238,675 i.hp. in oil engines to propel them or 54 per cent of the total horsepower of their propelling plants.

Of all the numerous types of propelling plant the following outstanding examples are to be noted. The recently launched White Star passenger liner *Brittanic* will be propelled by two ten-cylinder four-cycle double-acting engines of the Burmeister & Wain type, developing 10,000 s.hp. at 110 r.p.m. This is the largest engine with the same 33.071-in. bore by 59.055-in. stroke cylinder which was originally installed on the M.S. *Gripsholm* and of which more than 400,000 i.hp. have been built since. The four Dutch liners now under construction are to be propelled by two ten-cylinder (30 in. × 52¾ in.) two-cycle single-acting Sulzer engines developing 7000 s.hp. at 100 r.p.m., although a larger cylinder size has been repeatedly built up to seven cylinders, developing 7040 s.hp. at 100 r.p.m.[5] The other two notable propelling plants are the geared oil engines installed in the North German Lloyd liners *St. Louis* and *Milwaukee*. These are twin-screw vessels with two-cycle double-acting M.A.N.-type engines developing 3100 s.hp. at 225 r.p.m. (*St. Louis*) in six working cylinders of 19.097 in. bore and 25.98 in. stroke, geared to each shaft through the Vulcan hydraulic coupling.[6] On the M.S. *Milwaukee* the engines are coupled to the reduction gear direct.

Naval Oil Engines

The French submarine tender *Jules Verne*[7] has a propelling plant consisting of two eight-cylinder single-acting two-cycle Sulzer engines of the submarine type, one of which was ordered for experimental purposes in 1924 and developed on test 7000 b.hp. at 280 r.p.m., thus being by far the highest-powered engine of this type. These engines are installed so that they will develop only six-tenths of their speed and power in the ship.

The German faith in the oil engine as the most economical source of power served to develop it also into the lightest source of power for naval ships. The three German cruisers, the *Koenigsberg*, *Karlsruhe*, and *Koeln*, recently commissioned, have high-speed oil-engine cruising units in addition to their 65,000-s.hp. steam-turbine plant.

The now famous *Ersatz Preussen* received much of its military value in speed, guns, and protection through the ability of German engineers to develop an oil-engine propelling plant of 50,000 s.hp. which is actually lighter than any steam-turbine plant available.

Stationary Power Plants and Economics of the Oil Engine

Of the many hundreds of various stationary oil-engine power plants, the most notable is no doubt the installation of two double-acting two-cycle M.A.N. engines in a stand-by and peak-load plant at Henningsdorf, near Berlin, which was started last August. The engines have working cylinders of 23.622 in. bore and 35.433 in. stroke and can develop 11,700 b.hp. at 215 r.p.m. on a reported fuel consumption of 0.381 lb. per b.hp-hr. The engine is by far the largest engine using mechanical injection of fuel, and weighs only 55 lb. per b.hp. The simplicity of these large units is truly inspiring, but their resulting low cost, said to be $48 per kw., is also very important. Furthermore, with one man on watch the entire output of the plant (23,400 b.hp.) can be developed on two or three minutes' notice.

Railway Service

A total of 105 oil-electric locomotives were in service or on order in the United States and Canada by September 1, 46 of which were ordered during the year, as well as 35 switching locomotives ordered at one time by the New York Central for its New York west-side yards. These latter, in addition to the standard 300-b.hp. Ingersoll-Rand engine, have a 219-cell, 17-ton Exide battery and are arranged to operate also with outside current coming either through third rail or from an overhead collector. Of considerable interest is the Krupp locomotive for the Boston & Maine, scheduled for delivery before the year is over, in which a mechanical transmission with automatically operated magnetic clutches is used.

The Canadian National Railway has recently put into commission a large articulated locomotive housing in each cab one twelve-cylinder vee-type Beardmore four-cycle engine rated at 1340 b.hp. at 800 r.p.m.[8]

Supercharging and Two-Cycle vs. Four-Cycle

The old rivalry between two-cycle and four-cycle types of oil

engine continues. While even the Burmeister & Wain Company has developed a large double-acting two-cycle marine engine and another single-acting two-cycle high-speed engine which is being tried out in a locomotive and in a fishing boat; while the Werkspoor Company, and the Stabilimento Triestino (Italian licensee of Burmeister & Wain) have taken out licenses to build Sulzer two-cycle engines and Vickers has arranged to build two-cycle double-acting M.A.N. engines—while all of this seems to point one way, nevertheless the substantial development of supercharging of four-cycle engines gives this type of engine an advantage which cannot be overlooked, and its qualities have just begun to be appreciated. A recent paper[9] by the engineer-in-chief of the French Navy shows that even for a larger submarine propelling plant, substantial weight and space reductions are possible with supercharged four-cycle engines over all other possible types of oil engines.

A new type of supercharging became known during the year—the Werkspoor Company[11] utilized the underside of the piston of a crosshead type of single-acting engine for the purpose. Buchi[10] at the Swiss Locomotive Works and Rateau[12] in France both built exhaust-gas-driven turbo-blowers. The largest unit recently tested by the former comprised a 3000-b.hp. engine.

New Materials and Processes

The progress in the art of oil-engine building owes much to the perfection of the materials available for construction. The introduction of "nitralloy" steels having a glass-hard surface with a tough core has opened new possibilities for crankshafts (so far only small ones have been used), cams, pump plungers, and gears. Chromium plating was used in the Worthington engines for the Shipping Board, to produce a hard rubbing surface on a piston rod without affecting the elasticity necessary to withstand shocks of explosions. The extension of this process to cylinder liners is being perfected, and the building up of worn parts of plungers, valve stems, etc. may prove to be quite important for quick repairs.

The process of building up a lower cylinder head from steel parts by a copper soldering process[13] introduced by the German A.E.G. Co. for their large double-acting two-cycle engines,[7] will no doubt aid considerably in enhancing the reliability of large marine oil engines. Much experimental work is also being done to make welding of crankcases out of sheet-steel parts commercially feasible.

Oil-Engine Research

Spray research continues at the N.A.C.A. laboratories at Langley Field,[19] at Penn State College, and at the A.E.G. laboratories in Berlin. The effect of injection-tube length and diameter, injection pressure, valve-opening pressure, and initial tube pressure on the injection lag are being studied by means of spray photography at Langley Field. Work on the determination of the coefficient of discharge for small, round orifices as well as for multiple-orifice injection valves, continues.[14, 15, 16] The A.E.G. laboratories report investigations in progress on the size of oil drops in a fuel spray.

A very interesting method to determine whether engine, fuel, or lubricating oil is responsible for the difficulties experienced in burning certain varieties of fuel has been published by H. Jentzsch,[17] who developed an apparatus for testing the suitability of a given fuel by measuring the heat and oxygen required for self-ignition.

Gas Engines

The distribution of natural gas requires much power in gas-driven gas compressors—for the large pipe line from Louisiana to St. Louis twelve Worthington 1000-b.hp. units were installed during the year. The largest by-product source of energy is blast-furnace gas, and the Bethlehem Steel Company reports the installation of five of their 47-in. × 84-in. × 60-in. tandem gas-driven blowing engines. During the year the Allis-Chalmers Company designed and built two of their largest (60-in. × 64-in. cylinders) twin tandem gas engines, to be operated also on blast-furnace gas. The first plant in this country to be run successfully on sewage gas has been installed in Charlotte, N. C.,[18] where one 55-b.hp. and one 225-hp. standard Sterling gasoline engines were used. The Deutz Company installed an 1120-b.hp. power plant near Berlin working on sewage gas, and has another similar plant of 2100 hp. in course of construction.

Service Characteristics of Diesel-Engine Lubricating Oil

By A. E. FLOWERS[1] and M. A. DIETRICH,[2] POUGHKEEPSIE, N. Y.

Diesel-engine lubrication has presented difficulties owing to the high compression pressures and the high temperatures and to the great weight of engine parts. Results are given of a study of the progressive record of the characteristics of the lubricating oil used in a Diesel engine in regular service for about a year installed in a freight-switching locomotive running 23 hours of the day.

LUBRICATION of Diesel engines has presented serious difficulties, due to the high compression pressures, high temperatures, and great weight of the engine parts. Dr. Diesel himself has stated that his first engine ran only three revolutions, when first started, before stoppage was caused by the seizing of the piston rings; just long enough to demonstrate that it was possible to get ignition by compression. Service records of operating expenses usually have shown that the lubricating oil may cost from 10 to 25 per cent as much as the fuel oil.

It has seemed worth while to publish the results of a study of the progressive record of the characteristics of the lubricating oil in use in a Diesel engine in regular continuous service over a period of nearly one year. This Diesel engine was in operation on a combination battery-third-rail Diesel-electric locomotive employed upon switching service on the freight tracks of the New York Central Railroad on the West Side in New York City. The locomotive is in continuous service and the engine actually running about 23 out of every 24 hours.

Description of Engine

The engine upon which these tests were made was manufactured by the Ingersoll-Rand Company and installed on New York Central Railroad locomotive No. 1525. A view of the exterior of this engine is given in Fig. 1. The description is as follows:

Rating, 300 b.hp.; maximum speed, 550 r.p.m.; engine cycle, four-stroke; pistons, trunk type; number of cylinders, six; arrangement of cylinders, vertical; bore, 10 in.; stroke, 12 in.; piston speed, 1100 ft. per min.; mean effective pressure, 76 lb. per sq. in.; weight, without generator, 20,125 lb.; overall length, 12 ft.; overall height, 7 ft.; overall width, 3 ft. 3 in.; method of starting, using generator as motor on battery; fuel injection, direct solid injection; injection pressure, 3000 lb. per sq. in.; fuel distribution, single fuel pump and distributor.

The cylinder walls and cylinder head are jacketed and water-cooled. The water is cooled in turn by air-cooled radiators installed overhead at the end of the locomotive with blast fans for forced air-cooling.

The cooling water usually entered the engine at about 150 deg. fahr., and left at about 160 deg. fahr., and the lubricating oil was kept down to temperatures not very much greater than that of the cooling water.

Sponsored by the A.S.M.E. Special Research Committee on Lubrication and presented at its session during the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Description of Lubricating System

Lubrication of the Diesel engine is provided by a forced-feed oil pump taking oil from the crankcase, which held a supply of 54 gal., and delivering approximately 12 gal. per min. to the engine's main bearings. Holes in the crankshaft webs conduct oil to the connecting-rod bearings and up through holes in the connecting rod to the wristpin.

The cylinder walls obtained their supply of lubricating oil partly by splash from the crankcase, but mainly by overflow from the wristpin.

The lower end of the piston had the usual oil-wiper rings with drain holes leading back to the inner surface of the trunk piston.

The lubricating oil was continuously purified by the circulation of about 17 gal. per hour through a De Laval 17-H size disk clarifier operated at 7000 r.p.m. In this way the equivalent of the full content of the system was purified every three hours.

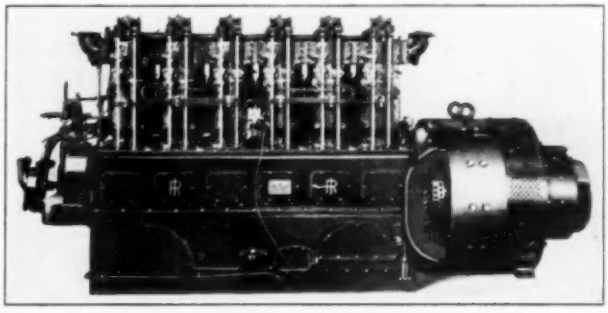

Fig. 1 Ingersoll-Rand 300-Hp. Locomotive Oil Engine Showing Oil Distributor Side and Generator

In some later runs the purifier throughput was changed to about 11 gal. per hour (i.e., a purification equivalent to about once in five hours) to try the effect of giving an even higher degree of clarification to the oil that was purified.

Test Methods Employed

All of the tests made upon the characteristics of the oil were carried out in accordance with the Standard or Tentative Standard Methods of Test adopted by the American Society for Testing Materials.

During the course of the work it was found desirable to improve upon the standard method for measuring the volume of sediment by means of the centrifuge, since a speed of 1500 r.p.m. on a 100-cc. test tube swung on a 17-in. circle took too long to settle out completely the carbonaceous sludge (about 10 hours being required). A new type De Laval test-tube centrifuge became available during the course of this work, operating at 4500 r.p.m., which reduced the settling time required to about one-fifth or less and in addition packed the sediment into a much smaller volume, thus giving a more representative figure for the amount of sludge.

Other methods of test, as well as further prolongation of the time of centrifuging the standard A.S.T.M. 100-cc. test tube at 4500 r.p.m., proved that *all* the sediment had been removed from the oil. The original red color was restored; in fact, even

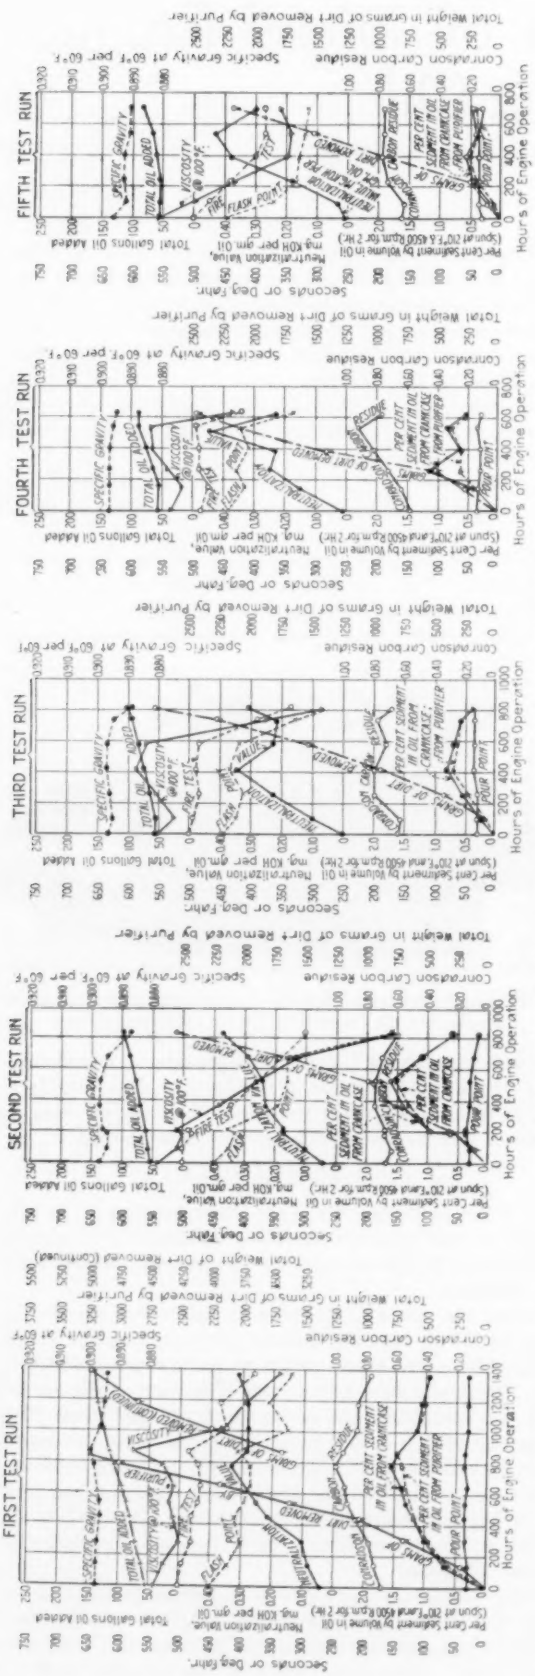

FIG. 2 PLOTTED CHARACTERISTICS OF THE OIL FOR FIVE RUNS

a lighter colored pale-yellow clear oil was obtained by extremely prolonged centrifuging.

During the course of this work it was found that for this kind of sediment the packing at 4500 r.p.m. gave a final sediment volume of only 62.3 per cent of that by centrifuging at the standard test speed of 1500 r.p.m.

By completely separating out all the sludge it was possible to make all the oil tests on samples of oil from which all sludge had been removed and so determine the characteristics of the residual oil itself.

CHARACTERISTIC CHANGES IN THE OIL

The changes (if any) in the characteristics of the lubricating oil are fully shown in the accompanying curve sheets plotted against hours of engine operation. The original characteristics of the new oil were as follows:

Specific gravity at 60 deg. fahr.	0.897
Flash point, deg. fahr.	450
Fire test, deg. fahr.	500
Pour point, deg. fahr.	30
Saybolt viscosity at 100 deg. fahr.	540
Saybolt viscosity at 210 deg. fahr.	66
Steam emulsion, S. E. No.	144
Neutralization No.	0.04
Color	Red
Conradson carbon residue	0.67
Sligh oxidation No.	9.7

The values for specific gravity, flash point, fire point, pour point, Saybolt Universal viscosity at 100 deg. fahr., carbon residue (Conradson method), neutralization number, and per cent sediment in the oil are given, as well as the total sediment removed from the oil and the quantity of oil used.

Examination of the curves for these tests (as well as comparisons with other engines) shows that service (when not affected by fuel dilution) tends somewhat to increase the gravity, fire and pour points, increase the viscosity and carbon residue, and to appreciably increase the neutralization number. The flash point tends to be decreased slightly, presumably as a result of cracking of some of the oil.

These changes are controlled, in part, by the amount of make-up oil added to the system, but for most of the runs recorded here the effect of fuel dilution was eventually predominant, causing an appreciable decrease of the gravity, flash, fire, and pour points, and of viscosity and a slight decrease in carbon residue.

Fuel dilution may come about in small part as direct leakage past the piston rings, but it would seem that this is negligible except when for some reason some cylinder fails to fire. Failure to fire on one cylinder occurred on Feb. 26, 1929, during the first run and resulted immediately in cumulative dilution, which finally reached a value of about 8 or 9 per cent. Fuel dilution may also result from pipe or pipe-fitting breakage, gasket leakage, or spillage around the engine. Whenever such causes were identified, they were of course corrected as quickly as possible.

Consideration of the increase of neutralization value and of the increase of carbon residue leads to the conclusion that to some extent the service in Diesel engines causes some oxidation as well as some cracking and some burning of the oil, not through any defect in the oil, but as a normal result of the necessarily severe service.

It will be noted that the engine crankcase was drained and refilled with new oil for each of the runs described herein, but there is no indication from the results of these tests that it may not be both feasible and desirable to leave the lubricating oil permanently in the engine without ever having to drain the crankcase, provided it is kept continuously clarified to a suitable degree.

When the sludge is removed at the same rate as it is produced the sludge content of the oil after filling the crankcase with new oil rises during the first part of the run and then stabilizes at a moderate value which is only so high as may be needed for the time and heating required to agglomerate the sludge to the settling and separating point.

During the course of these runs the sludge never reached 2 per cent by volume of the oil and usually the maximum was 1 per cent or less.

It may be desirable to remove the oil because of some accidental occurrence, such as fuel dilution, as in some of these runs, or the need for complete overhauling of the engine. When removed the oil may be given a simple but very effective treatment for reclamation, including a readily applied method for taking out fuel dilution, if any be present.

Character of the Sludge From Diesel-Engine Lubricating Oil

The sludge that separates from Diesel-engine lubricating oil is mainly carbonaceous matter. From a new engine, however, large amounts of free iron (fine chips and filings or initial-wear particles) and sand (presumably core sand from the inner walls of the castings) may be found. Some sand, probably picked up from the roadbed and carried into the engine through the breather connections or with the oil used for combustion, seemed to be present throughout the runs. As the run proceeds, both metallic oxides (principally iron with small amounts of copper, tin, and antimony) and silica decrease from their initial values to the practically constant and quite small proportions of 1 to 2 per cent of the oil-free total for silica and 5 to 10 per cent for metallic oxides. The carbonaceous matter is absent from new oil at the start of a run, reaches a maximum after several hundred hours, and then decreases or remains practically constant at values of 0.5 to 1.5 per cent of the volume of the oil. Even when packed tightly the sludge carries with it, in the interstices, a large proportion of oil, amounting to about 50 per cent of the total sludge, by weight and slightly more by volume. The sludge and the oil itself were practically free from water.

Fig. 4 Tabulated Data for the Analyses of the Sludge

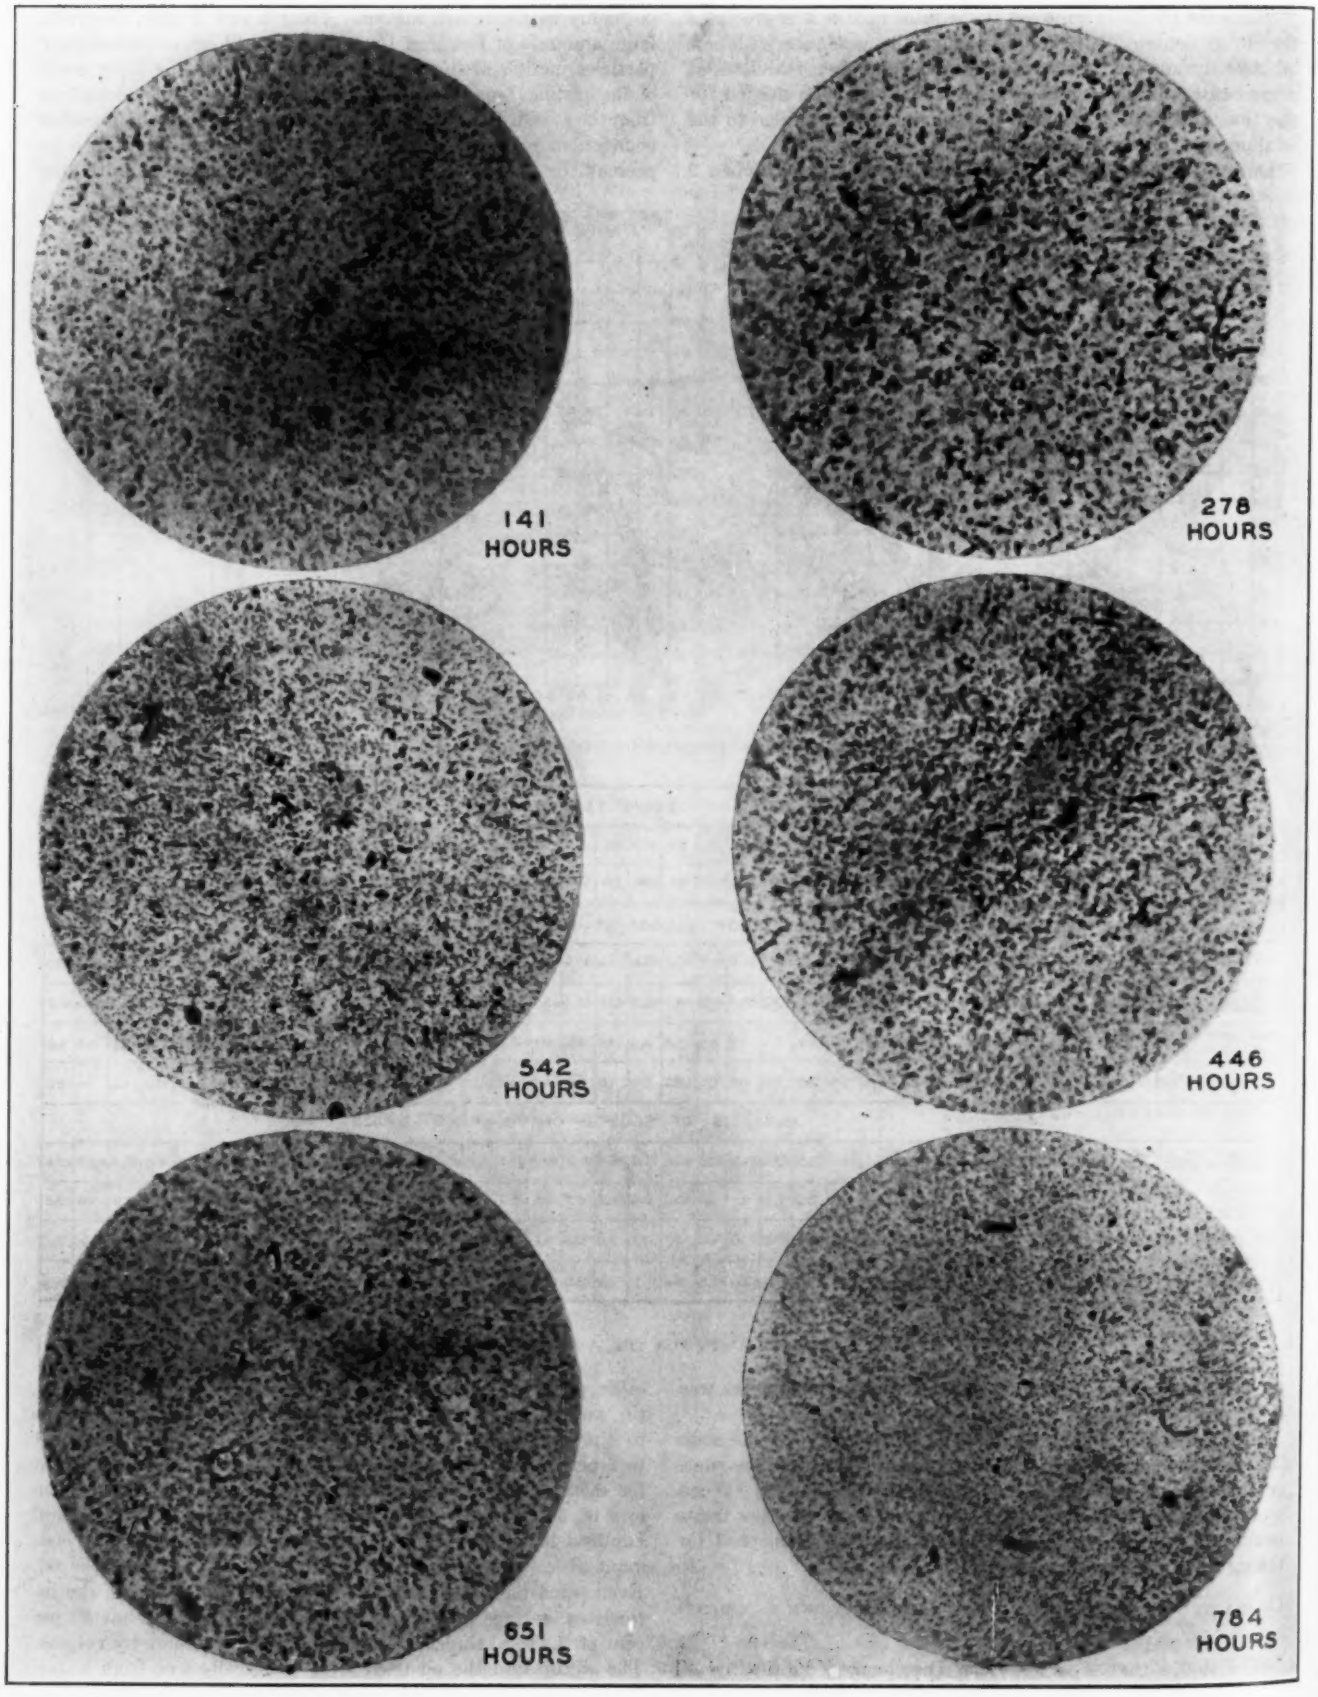

FIG. 5 (*a*) PHOTOMICROGRAPHS OF LUBRICATING OIL REMOVED FROM CRANKCASE × 470

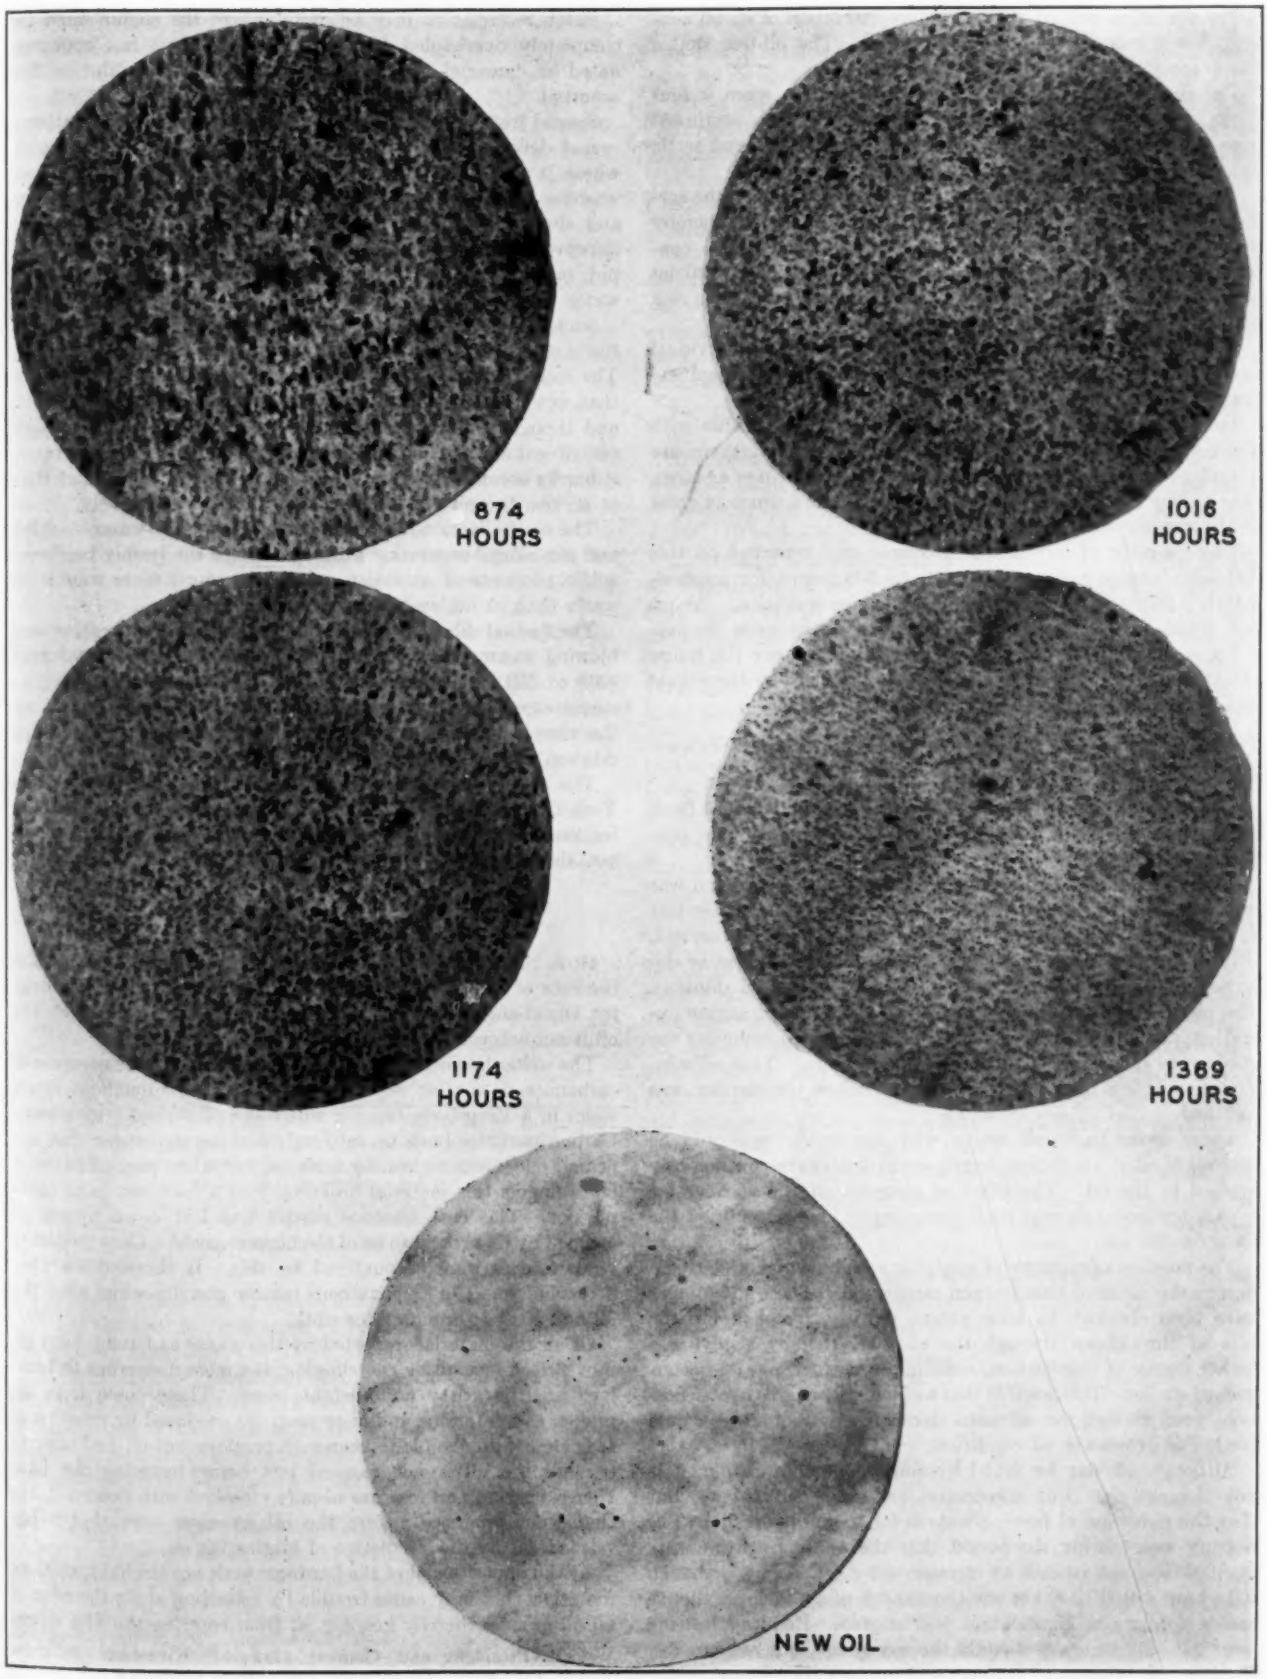

FIG. 5 (*b*) PHOTOMICROGRAPHS OF LUBRICATING OIL REMOVED FROM CRANKCASE × 470

The sludge, as settled out and before extraction of its oil content, has a gross specific gravity of 1.11. The oil-free sludge has a specific gravity of 1.2 to 1.5.

The sludge, especially the carbonaceous matter when it first forms, consists of extremely minute particles. With continued time and heating these particles tend to agglomerate and settle out, or are removed by centrifuging.

The higher the degree of clarification applied to the oil the earlier in the agglomeration stage can the sludge be removed, thereby serving two useful purposes—first, stabilizing the sludge content at lower values and, second, keeping whatever particles may be present nearer the colloidal state and so less able to clog passages, settle on walls, or wear the running parts.

The appearance of the sludge and the size of the individual particles are shown in the photomicrographs with a magnification of 470 times.

Individual particles (or groups of particles) are visible with dimensions of one-thousandth of a millimeter, and there are irregular-shaped agglomerates that are five to ten times as large, thus having a mass one hundred to one thousand times as great as the smaller visible particles.

The quantity of oily sludge produced and removed on this 300 b.hp. engine amounted to 300 to 400 grams (or approximately 0.65 to 0.90 lb.) per 100 hours of engine operation. About half of this sludge is the oil which fills the space between the particles, so that on the dry basis 150 to 200 grams per 100 hours of engine operation of "dry sludge" was produced by the engine and removed by the continuously operated purifier.

Purification and Reclamation of Diesel-Engine Lubricating Oil

The engine crankcase had been drained and refilled with fresh new oil monthly prior to the installation of the continuous centrifugal clarifier.

In the first run the oil was kept in service ten weeks and was removed primarily in order to allow the starting of another test and to get a check upon the progress of the changes observed. Other runs were shorter, not because the oil had sludged or deteriorated, but because of engine changes or fuel-oil dilution. The make-up oil needed was 6 gal. per 100 hours of engine operation, and only 10 gal. per 100 hours was needed including the oil drained out at the end of the 10-week run. This oil consumption is less than half that needed before the clarifier was installed.

There seems to be no reason why the crankcase should be drained of oil, if a sufficient degree of clarification be continuously applied to the oil. The effect of stoppage of the clarifier for even a few hours showed itself immediately in the results of the tests on the oil.

The possible advantages of applying a high degree of clarification to the oil have already been mentioned. These advantages have been checked, to some extent already, by changing the rate of throughput through the clarifier, thereby applying a higher degree of clarification, resulting in cleaner oil and better-packed sludge. It is possible that a still higher degree of clarification, even though the oil were clarified less frequently, would further improve the oil condition.

Although oil may be saved by continuous clarification, it is not thought that this constitutes its major advantage, but that the reduction of bearing wear is far more important. The bearing wear during the period that the oil was continuously clarified was not enough to measure after ten weeks, although it had amounted to about one-thousandth of an inch per month before continuous clarification was started. Reduced bearing wear not only increases directly the engine life, but reduces cost of labor for take-up of bearing and outages for repairs.

Batch reclamation may be useful where the engine must be completely overhauled or where some accident has contaminated or damaged the oil or where fuel or other dilution has occurred.

Special tests have shown that heating and allowing a settling period definitely assist in agglomerating the sludge to a point where it is readily removable. Other tests have shown that washing with clean boiling water and then removing the water and sludge together in a centrifugal separator tremendously improves the centrifuging process, allowing purification throughput rates about 100 times greater than purification without water washing.

Such simple treatments will restore all the original properties except color and to some extent neutralization number. The reclaimed oil is clean and free of sludge, but usually darker than new oil. It is not believed that color, per se, is important, and though it might be restored by applying excessively high centrifugal clarification treatment at very low throughput rates, it hardly seems economically justifiable in view of the fact that in service the oil will be darkened almost immediately.

The neutralization number is improved by the water-washing and centrifugal-separation process, because the freshly produced acidic products of oxidation, which are much more soluble in water than in oil, are removed.

The fuel-oil dilution, if any, may be removed by heating and blowing steam directly through the oil. A high temperature (200 to 250 deg. cent.) and the use of superheated steam (i.e., steam expanded down from 250 lb. per sq. in.) greatly reduce the time required and the steam consumption needed for fuel dilution removal.

The authors are indebted to the representatives of the New York Central Railroad and of the De Laval Separator Company for much direct assistance and for facilities afforded to carry out the work.

Discussion

H. A. S. Howarth.[3] It would be interesting to learn whether the rate of sludge formation with a given oil is much different for Diesel-engine service than for some other one in which the oil is not subjected to such heated wall contacts.

The writer had occasion many years ago to note the presence of carbonaceous matter deposited by warm oil throughout interstices in a Kingsbury bearing where the oil flowed very slowly. Carbon particles built up into ugly looking structures that appeared dangerous to bearing surfaces, but when pressed between one's fingers this material broke up into a harmless impalpable powder. This carbonaceous matter was laid down by an oil claimed by its makers to be of the highest grade. Only moderate temperatures were encountered by this. It threw down very little sludge. The carbonaceous matter was deposited after the oil had passed through filter cloth.

Of all the materials reported by this paper as having been removed from the oil by centrifuging, the most dangerous to bearings are the gritty and metallic ones. These come from oil piping, cast interiors, and loose particles produced by machining. It is almost impossible to keep such particles out of the bearings, because the oil is not cleaned just before entering the film. Hence bearing surfaces are usually streaked with fine scratches that were produced before the oil passages were thoroughly washed out by the circulation of lubricating oil.

At the opposite end of the hardness scale are the light, cottony materials that may cause trouble by collecting along the edge of an oil groove, thereby keeping oil from entering the film space.

[3] Vice-President and General Manager, Kingsbury Machine Works, Frankford, Philadelphia, Pa. Mem. A.S.M.E.

Such substances are probably adequately removed by fine wire screens placed as near the bearings as practicable.

When installing Kingsbury thrust bearings in the days when central-station oiling systems were the rule, we advised the user to heat the oil in his system, then to bypass the bearings and to circulate the oil until the filters showed no injurious materials present. Even then we advised the use of muslin bags over the ends of the oil inlet pipes within the bearing housing for a few weeks.

Users of bearings in high-grade machinery understand fairly well today that they must keep dirt out of the oil. Yet it is a common experience to see mechanics in filthy overalls standing over bearings and lifting clean parts in or out. And they are trying to keep the bearings clean. The sum total, however, of the care exercised by those dealing with fine bearings must be quite satisfactory nowadays, because the failures of such oil-film bearings are indeed very rare occurrences.

H. C. Dinger.[4] This paper is of special interest as indicating in a rather definite manner that the more or less continual clarifying of the Diesel lubricating oil and the addition of new oil to make up for leakage, oxidation, and evaporation will enable the lubricant to be kept in excellent condition without requiring frequent dumping and replenishment of the whole sump. The contamination to be expected is much less than with gasoline engines because of the absence of the light ends.

The Engineering Experiment Station, Annapolis, has checked the condition of lubricating oil on Navy submarines covering considerable periods, and the writer would like to offer some general observations as reflected by those investigations which conform rather closely to the results reported in this paper.

The following conclusions were drawn from the examination of a large number of used Diesel-engine lubricating oils from submarines, the submarines being equipped with centrifugal purifiers:

(*a*) A slight increase in specific gravity of the oil
(*b*) A considerable decrease in flash point in both open- and closed-cup apparatus
(*c*) A considerable decrease in fire point
(*d*) Pour point not much affected
(*e*) A slight decrease in viscosity
(*f*) The oil is darkened in use, but not to nearly as great an extent as encountered in internal-explosion engines (gasoline engines)
(*g*) No development of mineral acidity in the oil
(*h*) Neutralization number, precipitation number, and carbon residue are increased to practically the same extent as encountered in a force-feed turbine lubricating-oil system
(*i*) The nature of the carbon residue in the oil is not changed, nor is there any appreciable increase in ash
(*j*) The non-emulsifying properties of the oils were considerably affected
(*k*) Not any of the samples contained more than a trace of water.

It appears from all the information available that the contamination of the used lubricating oil of Diesel engines from the fuel is, in general, very slight.

The foregoing conclusions are in fair agreement with the results obtained by Dr. Flowers and Mr. Dietrich and show that centrifugal purification of the lubricating oil of Diesel engines is fairly satisfactory and that complete renewal is necessary only at special times when a complete cleaning of the crankcase is desired.

Eugene P. Kiehl.[5] The Diesel engines to be described by the writer are in operation as power-generating units, operating continuously at 90 per cent load factor, at the Philadelphia plant of the Atlantic Refining Company. These engines have been in continuous service for approximately four years, coming down only for repairs.

The engines upon which this information is based were manufactured by the Rathbun-Jones Engineering Company for the Ingersoll-Rand Company and were installed in No. 1 power house. The description is as follows:

Rating, 840 b.hp.; speed, 214 r.p.m.; engine cycle, four-stroke; piston, trunk type; number of cylinders, six; arrangement of cylinders, vertical; bore, 19½ in.; stroke, 24 in.; piston speed, 856 ft. per min.; mean effective pressure, 68 lb. per sq. in.; overall length, 25 ft. 6 in.; overall width, 11 ft.; overall height, 13 ft.; method of starting, air; direct solid injection; injection pressure, 3000 to 5000 lb. per sq. in.; fuel distribution, single-feed pump and distributer per engine.

The cylinder walls and cylinder head are jacketed and water cooled. In winter this water is recirculated.

The cooling water enters the engines at about 80 deg. fahr. and leaves at about 100 deg. fahr., the lubricating oil being kept down to temperatures not very much greater than that of the cooling water, 110 to 130 deg. fahr.

Lubrication of these engines is provided by an oil pump taking oil from the crankcase and delivering it to the piston sump tank, from which the oil is circulated to the piston cooling pump and the centrifuge. Oil is fed to the bearings by gravity through sight feeds. Holes in the crankcase webs conduct oil to the connecting-rod bearings, and through holes in the connecting rod to the wristpin.

The cylinder walls and camshaft bearings obtain their lubrication chiefly by splash from the crankcase. The lower end of the piston has one oil-wiper ring with the drain holes leading back to the inner surface of the trunk piston.

The lubricating oil is continuously purified by circulation through a Sharpless clarifier operated at 17,000 r.p.m. for six hours per day on each of the four engines. The amount continuously purified is 5000 gal. per 24 hours.

A weighed sample was dissolved in special solvent (70-deg. naphtha) and filtered through a weighed Gooch crucible. The latter was dried at 212 deg. fahr. and weighed. This residue was then washed with benzol, dried at 212 deg. fahr., and weighed.

A separate sample was ashed, the ash washed on a filter paper with hot water, and the filtrate tested for sodium sulphate. The water-insoluble portion was digested with hydrochloric acid, the acid-insoluble portion was calculated as silica, while the soluble portion was taken as combined oxides.

The portion soluble in naphtha was calculated as oil, while that insoluble in naphtha but soluble in benzol was calculated as asphaltic. Carbonaceous material was taken as 100 (ash plus asphaltic plus oil).

With this method of testing it was impossible to test the oil contained in sludge for its characteristics. The original characteristics of the new oil are as follows:

A.P.I. gravity at 60 deg. fahr.	26
Flash point, deg. fahr.	440
Fire test, deg. fahr.	505
Saybolt viscosity at 100 deg. fahr.	504
Saybolt viscosity at 210 deg. fahr.	63
S. E. No.	120
Color, N.P.A.	4½–4¾
Conradson carbon residue	0.460
Fuel dilution (no record kept)	.....
Pour point, deg. fahr.	25

The engine has never had the oil completely renewed at one time as there has been no indication of the desirability of changing.

The analysis of the sludge as removed from the bowl of the purifier is as follows:

[4] Captain, U. S. Navy, Officer-in-Charge, Engineering Experiment Station, Annapolis, Md. Mem. A.S.M.E.

[5] Power Engineer, Atlantic Refining Company, Philadelphia, Pa. Mem. A.S.M.E.

	Oil	Asphaltic	Carbonaceous	SiO_2	Na_2SO_4	Combined oxides
Sludge from centrifugal bowl (4 p.m., 11/26/29)	48.05	4.41	43.12	0.533	0.343	3.54
Sludge from centrifugal bowl (midnight, 11/26/29)	47.18	5.18	43.80	0.322	0.291	3.22
Sludge from centrifugal bowl (8 a.m., 11/27/29)	49.23	8.11	39.93	0.379	0.305	2.05
Average	48.15	5.90	42.28	0.411	0.313	2.90

The sludge that separates from Diesel-engine lubricating oil is chiefly carbonaceous matter. The sludge as removed from our separator has the consistency of soft rubber and carries with it approximately 50 per cent of oil.

The quantity of sludge produced and removed on these 840-hp. engines amounts to 12.3 lb.[6] per 24 hours of centrifuging, including the oil. When first installed, the bowl of the centrifuge was removed and cleaned once a day, about 8.5 lb. of sludge being deposited. When the bowl is cleaned once every eight hours, we get an increase of 2.8 lb. per day, or 33 per cent by weight.

Authors' Closure

Mr. Hersey's comments suggested by Dr. H. T. Kennedy of the Bureau of Standards requested information upon the fuel oil used. Information in regard to this is given, having been worked up since the presentation of the paper. We do not have, however, information upon the mixture ratio employed for the engine.

The characteristics of the fuel oil used on Diesel-electric locomotive No. 1525 of New York Central Railroad are reported as follows:

Property	Unit	
Specific gravity at 60 deg. fahr.	Water at 60° F.	0.844 = 36.2° A.P.I
Flash point	°F.	215
Fire test	°F.	250
Pour point	°F.	−10
Saybolt viscosity at 100 deg. fahr.	Sec.	37
Saybolt viscosity at	Sec.	.....
Steam emulsion, S. E. No.	Sec.	.....
Neutralization No.	mgKOH/gm	0.28
Color	....	.....
B.S. and water by centrifuge, bottom drain sample	%	0.62
B. S. centrifuge	%	.....
Water centrifuge	%	.....
Water distillation	%	.....
Conradson carbon residue	%	0.04
Slight oxidation No.	mg/10gm	
Sulphur	....	0.262

The sulphur was determined by the bomb method, using an

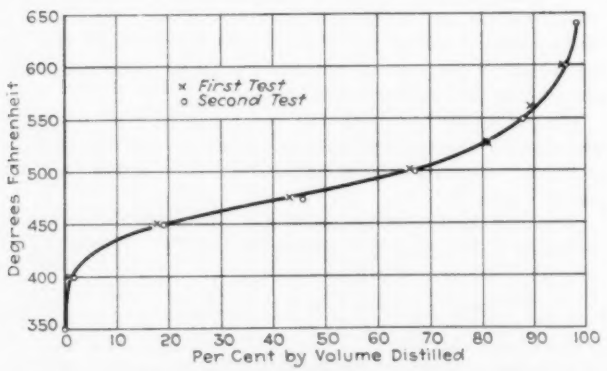

Fig. 6 Distillation Curve of Fuel Oil Used on New York Central Railroad Locomotive No. 1525

Emerson calorimeter. The distillation curve of the fuel oil is given in Fig. 6.

There is no evidence that dilution in the lubricating oil occurs in the way and to the extent found in gasoline-automobile engines (except in the case of a cylinder failing to fire), and dilution does not seem to occur under normal operating conditions, so far as we have been able to find.

The examination of the character of the sludge in terms of its solubility in benzol, chloroform, etc., has been made[7] since the presentation of the paper and is given in the report herewith.

The samples analyzed were taken during the test runs on locomotive No. 1525 on February 26 and March 19, 1929. The analysis is as follows:

ANALYSIS OF SLUDGE ON OIL-FREE BASIS

	Feb. 26	March 19
Benzole-soluble material, per cent	20.6	27.9
Choloroform-soluble material, per cent	3.5	5.1
Insoluble carbonaceous material, per cent	71.4	60.0
Metallic oxides, per cent	3.9	6.0
Silica, per cent	0.6	1.0

The high percentage of insoluble carbonaceous material indicates that the sludge is formed more by cracking of the oil than by oxidation.

The authors were impressed by the statement that, in Dr. Kennedy's opinion, settling, if sufficiently prolonged, would render the lubricating oil essentially as good as new, and the further confirmation of this new point by Captain Dinger.

The authors are obliged to Mr. Hall for his observations on the quantity of sludge removed from the lubricating oil of 840-hp., 214-r.p.m. engines of 12 lb. per 24 hours at first, 8 lb. per 24 hours later, when using a lubricating oil of 504 seconds viscosity at 100 deg. fahr., and his further observation of the desirability of frequent cleaning of the centrifuge bowl.

The answer to Mr. Howarth's question as to the collection of sludge on the crankcase walls is that such deposits occurred before centrifugal purification was practiced, but deposits did not occur afterward.

It was interesting to hear from Mr. Howes that where the crankcase is separate from the cylinder he had observed more sludge produced in the crankcase than on the cylinder walls, and the concurrence in this by Mr. Codding.

We have checked the condition of the crankcase walls on a large marine engine with a separate crankcase chamber after one year's service. In this case a large centrifugal oil purifier was in operation, and the crankcase walls were as clean as new surfaces.

Mr. Codding's question as to rate of addition of oil make-up is answered by the plotted curves, which show a fairly frequent addition of make-up oil, in moderate amounts compared to the volume of oil space in the crankcase.

Dr. Dickinson appears to consider that there may be some advantage in having a large volume of lubricating oil in the crankcase and so allowing time for impurities to settle out. We are not sure that this is the best practice when a powerful centrifugal clarification can be employed continuously, although it may be useful where no clarification is available.

There would seem to be some advantage in keeping the oil volume small when vigorously clarifying it, as the total volume of oil is then more frequently clarified and the fully clarified oil is contaminated by a smaller volume of dirty oil when returned and mixed with the mass of oil in the crankcase. The ideal arrangement would seem to be to feed only clarified oil to a pressure-lubrication system, to eliminate splash lubrication, and to have practically no oil at all in the crankcase. In such a system the amount of oil would be restricted to the minimum value and would be large enough only to insure against the sudden loss of all lubricant through an unobserved leak.

[6] Approximately 6 per cent of the make-up added.

[7] Report made on December 18, 1929.

The Gas Engine and Its Application in Oil-Field Engineering

By GEORGE L. REID,[1] OIL CITY, PA.

The paper presents specific information in regard to engineering problems and progress relative to the processes of oil lift. Drilling is accomplished by two methods in the United States. The older one is by the cable tool, standard, or percussion system, and the later one is by the rotary system. Engineering in respect to drilling is on a firm basis. The geologist has predetermined the structures. The tools and power requirements are known within a close factor of accuracy. In order to reduce the tremendous losses sustained through dry holes or wells which fail to pay for themselves, it was necessary that scientific methods be developed.

LESS engineering data are available in a usable form concerning the lifting of oil than in any other branch of the oil industry. Records often prove of little use, for no property presents the same problems as another and each well has its own variable load which must be handled.

Fully 50 per cent of the total of $11,300,000,000 invested in the oil industry is in the machinery of production. For engines alone the production end is spending $30,000,000 annually.

Engaged in actual oil life there are about 150,000[2] engines of all types, and these are being augmented at the rate of 15,000 per year. Of a total of 2,205,000 horsepower being delivered by internal-combustion engines in the oil fields, approximately 80 per cent, or 1,780,000 horsepower, is being delivered by the single-cylinder horizontal-type gas engine. Diesel engines in the oil industry are delivering 252,250 horsepower, steam 178,750 horsepower, and other internal-combustion engines of multicylinder type 372,820 horsepower.

The Single-Cylinder Horizontal-Type Gas Engine

The single-cylinder horizontal-type gas engine has been particularly adaptable to the oil fields because of its ruggedness, simplicity, flexibility of operation, compactness, and because it uses a fuel which is produced within easy access of the base of operations and does not necessitate the power plant upon which the operation of the steam engine or the electric motor is absolutely dependent.

The vertical engine has not won a place in the oil field so far as production methods are concerned. In the pipe-line transportation of oil multicylinder gas and Diesel engines have an established position. The inaccessibility of the vertical engine to field repair and maintenance has been the largest factor against its more general adoption.

The fundamental principles of engineering and thermodynamics concerning the gas engine have not changed materially in regard to the single-cylinder horizontal-type gas engine. However, the manufacturers of these engines have kept well abreast of the times in the use of the best available materials.

[1] Joseph Reid Gas Engine Company.

[2] From survey prepared by *Oil Field Engineering*. The figures following are computed from this survey.

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of the authors, and not those of the Society.

The Four-Stroke-Cycle Engine

The four-stroke-cycle engine still operates on the later principles adopted by Otto. It has, however, been necessary to sacrifice some of the high fuel economy of the older engines to make for a more accessible engine, with ease of operation and upkeep in the field. This decrease of thermal efficiency is due in part to the lowering of compression pressures and the position of the inlet and exhaust valves. Because there is a wide variation in the B.t.u. value of the gas that may be employed in an engine, it has been advisable to keep the compression pressures within such a range as will give a safe compression pressure even with a rich gas. Yet the engine must also be able to deliver a maximum of horsepower with a gas as low as 500 B.t.u. The high range of B.t.u. value rarely exceeds 1500. These values apply to natural gas. What has been stated above concerning the relation of fuel values and thermal efficiency in relation to compression pressures stands equally true for the two-stroke-cycle.

However, to revert to the four-stroke-cycle and the position of the valves, on the four-stroke-cycle single-cylinder horizontal-type gas engines which have an enclosed bedplate it has been necessary to have a separate combustion head so that the piston might be removed readily for inspection and repair. In order to accomplish such removal with a minimum of labor it has been desirable to keep the valve passages within the cylinder proper. Due to the arrangement of the stud holes for the combustion head the valve passage may form a small pocket which tends to lessen compression, and unless great care is used in design there is a liability to dilution of the fresh charge by pocketed exhaust gases. In cylinders of 12 in. in diameter and above, this is more easily taken care of as there is ample room for the bolt circle of the studs, thus allowing a minimum valve passage into the cylinder space.

One class of engines which does not have an enclosed bedplate nor a removable combustion chamber is operating at a thermal efficiency varying from 25 to 28. This particular class is using a valve conceived by Mr. S. B. Daugherty which is worthy of description. The governor acts upon a gas and air valve which admits the correct proportions of air and gas into the main inlet valve. This valve is so constructed that the gas is admitted to the air through slender orifices in copper tuyeres which are inserted in the gas passage of the valve case. This system gives a homogeneous mixture, and engines equipped with this type of valve are delivering the best thermal results relative to the single-cylinder horizontal-type engine of which the author knows.

The Two-Stroke-Cycle Engine

The two-stroke-cycle gas engine has probably met with more radical change of design than the four-stroke-cycle.

The two-stroke-cycle was devised by Clerk in England, where he built his first successful engine in 1878. In order to obtain an impulse every revolution he used an auxiliary cylinder which forced the charge into the motor cylinder. Scavenging was accomplished through ports as is common in the two-cycle engines of the present day. In the first engine he tried to force the charge into the motor cylinder at the pressure of compression. This was found to be a useless expenditure of energy, and in a later engine the pumping cylinder operated at a pressure sufficient only to

force it into the motor cylinder. The pump cylinder in the later engine was actuated by means of a wristpin inserted in the flywheel. Clerk, however, was never entirely successful in governing his engine, and it is of interest to note in one of his reports that his engine actually made 300 revolutions without a miss or backfire.

The first gas engine successfully applied to oil field uses was built at Oil City, Pennsylvania, in 1893 and put to work in the adjacent oil fields. Since that time the gas engine has been a fundamental factor in the production of oil.

This engine followed the design of Clerk, but was much more simple in design and in operation. It was also successfully governed, and positive ignition was obtained by a hot tube.

The immediate success of this engine and the continued demand for it gave the two-stroke-cycle engine a firm and lasting grip on the oil industry. Other American manufacturers entered the field using a modified European design which accomplished the function of the pumping cylinder in the crankcase rather than the use of the extra cylinder. Present practice has modified this, and a stuffing box is inserted between the crosshead guides and the joint of the cylinder and bed at a point best suited to the design. The working stroke of the piston thus serves also as a pumping stroke on the ingoing charge and forces it into the cylinder through ports above the exhaust ports.

The thermal economy of this engine as compared to the pump-cylinder type is not as high. It is the author's opinion that a pumping cylinder gives a cleaner charge, and is more positive in its injection, while compression-case injection is quite apt to inject the charge into the cylinder still retaining some of the exhaust gases.

However, the compression case style of engine has much to merit it as the most popular type of engine, and it is most widely used at the present time. Its design permits it to be entirely enclosed, thus preventing loss of oil and the entrance of foreign abrasive matter. The combustion head is easily removed and the piston withdrawn, as in the four-stroke-cycle engine, for inspection and repair. Journal bearings, crankpin, and crosshead guides and pin may be splash-oiled, thus eliminating hand or mechanical oiling devices.

In both the two- and the four-stroke-cycle engines the ratio between bore and stroke is somewhat less, following the general trend of automobile practice. Bearing sizes have materially increased due to the heavy loads that they must sustain. The tendency toward the large-diameter short-length bearing is becoming more pronounced, as there is less tendency for bend in this type and an increase in the projected bearing surface of such a bearing. Roller bearings are coming into use, but it cannot be stated that they have become generally adopted. This is not due to any mechanical obstacle, but the demand for this type of equipment has not yet reached the stage where it has warranted change of design entirely profitable to the manufacturer.

In the past five years there has been an increasing demand for a single-cylinder horizontal two-stroke-cycle engine which would run at speeds ranging from 180 to 450 r.p.m. without knocking or backfire. Formerly a speed of about 250 r.p.m. was the limit in oil-field work, and the new demands for quietness caused research into the mechanics of the rotating and reciprocating members of the engines to determine how these knocks could be eliminated at the high speeds of the horizontal engine.

One manufacturer lightened these members 300 lb. and eliminated a knock that had occurred at 257 r.p.m., and there was no return of the knock until a speed approximating 380 had been reached. Due to the fact that the parts had been lightened to the point of safe operating limits a force-feed oiling system was developed upon the recommendation of L. H. Morrison. This system supplies oil at 50 lb. pressure to the journal, crankpin, and crosshead-pin bearings, and no knock has been detected at speeds a little in excess of 500 r.p.m.

Application of Single-Cylinder Horizontal-Type Gas Engine

The single-cylinder horizontal-type gas engine is applied to the oil-field production division in several ways, namely:

(*a*) Drilling
(*b*) Swabbing
(*c*) Pumping an individual well
(*d*) To drive a pumping power
(*e*) To drive compressors for air lift and repressuring of oil sands
(*f*) To drive water pumps for water-flood processes.

Wherever methods (*e*) and (*f*) are employed, method (*d*) must also be used.

Because of its range of speed and extreme flexibility the two-stroke-cycle engine is used almost exclusively on methods (*a*), (*b*), and (*c*). Method (*d*) also largely employs the two-stroke-cycle engine, but there has been a decided trend toward the four-stroke-cycle in the last few years.

Drilling by the cable tool or percussion system necessitates a range of speed and a variation of power that is found in the two-stroke-cycle engine. During the actual drilling operation, where it is only necessary to impart an oscillating motion to the walking beam, the engine is run at a speed of from 150 to 180 r.p.m., depending upon the horsepower required. When the hole has been drilled the additional depth allowed it by the temper screw (about 8 ft.) the walking beam is disengaged and the bullwheel shaft, which acts as a hoist drum, is brought into use to lift the tools from the hole. The engine is at once speeded up to over 450 r.p.m., and the tools are pulled from the hole. The bailer or sand pump is then let into the well, and when it has become filled with the detritus from the drilling the engine is again thrown wide open and the bailer is pulled up. Thus there is demand for speed range and at the same time an increasing power range with as near a constant torque as can be maintained at the higher speeds. When it is considered that the entire system of drilling tools must be lifted from a depth that steadily increases to 3000 or 4000 ft., and may contain water for much of its depth, it is at once obvious that tremendous strains are imposed upon the engine and that it is vital that there be no stalling with the load.

Swabbing Method

Method (*b*), or swabbing, is employed when a well ceases to flow or where the production is too great for the usual pumping unit.

The swab is lowered and the fluid passes through a check valve and emerges above the swab. The power is then pulled from the hole. Damage has been done by inserting the swab too far into the fluid and then attempting to withdraw it suddenly. Derricks are sometimes pulled down or other equipment damaged. An unloader now automatically releases a too heavy load.

Swabbing often continues over long periods with the engine racing at full speed. Engines rated at 45 b.hp. at 180 r.p.m. are being driven at 450 to 500 and delivering 90 b.hp. to handle these loads.

When the swabbing recovery becomes no longer profitable, method (*c*), or pumping, is used. The engine drives the walking beam at 20 to 35 strokes per minute, the length of the stroke varying from 24 to 60 in. The bull wheel is maintained to pull the pumping equipment. Here again a variation of speed and power is necessary, and the two-stroke-cycle engine is the most flexible and applicable unit.

As the oil diminishes it no longer is profitable to pump with an

individual engine. Here the pumping power, or method (*d*), comes into use as a vital piece of machinery. It will be described farther on. This unit is driven either by the two- or four-cycle engine, but is most satisfactorily operated by the four-cycle engine.

Repressuring the Oil Sands

Eastern oil fields have shown a constantly diminishing production for many years. When it finally was realized that gas was the carrying agent of oil through the sand, operators forced it back into the oil sands at the necessary pressures for penetration. Where there was not enough gas, compressed air was used.

Compression, method (*e*), is accomplished by the gas engine driving a standard compressor either directly or by belt. The air or gas is forced at pressures from 60 to over 200 lb. Usually several months, and in some cases several years, elapse before improvement in production is shown. It may amount to 500 per cent and will continue for considerable time.

The best practice as regards power for compressors requires a four-stroke-cycle engine. This type makes for steady running and a constant volume and pressure delivery of air.

Using Water Pumps

An important method used in depleted Eastern sands is the water-flood method (*f*). Water is introduced into four surrounding wells at pressures from 300 to 2000 lb. depending on the porosity of the oil stratum. This forces ahead of it the gas in considerable quantities and then the oil. This so-called five-spot system is now causing a production of 12,000 barrels of oil to $1^1/_2$ wells per acre.

The four-cycle engine is used in sizes from 25 to 100 hp. to drive water pumps for flooding. In both the air and water flood 24-hour service is imperative. As the sands become impregnated with air and water, the loads increase and greater demands come upon the engine.

The Pumping Power

As previously stated the oil recovered by methods (*e*) and (*f*) is dependent on method (*d*) to raise it from the hole. The power consists of a gear or wheel supported by a vertical shaft and revolving in a horizontal plane. The hub is attached to two eccentrics, in usual practice, which act as cranks, also revolving horizontally, thus imparting the reciprocating motion necessary. The bandwheel type of power will be dealt with because of its widening use and because the demand for larger diameters of bandwheel presents a greater engineering problem. The 24-ft. wheel is the largest size in popular use.

A bandwheel power consists of a base and an upright shaft. Formerly it was the practice to mount on the shaft the bronzed bushed eccentrics and the wheel hub. The rim of the bandwheel was held in place by spokes running to the hub. Stiffening members, driver angles, or channels impart the motion of the wheel to the center of the power. The weight of the hub and eccentrics or the rotating parts is borne by a bearing plate or disk in the base. Upon this plate is exerted a force of about 40 lb. per sq. in. of projected area. In one example of a bushed power there is a total projected area of 461 sq. in. Upon this a 40-hp. engine will exert a pressure of 2880 lb. per sq. in. of projected area.

The demand for a power to handle deep wells with a heavy fluid load and a long stroke caused considerable change in power design. The adoption of roller bearings permitted more massive parts.

Progress of Design

In the progress of design, the shaft, which is treated as a beam supported at one end, has retained the same relative function as previous practice had assigned to it. This is also true of the base. The sleeve which is slipped over the shaft relieves the shaft of much of the strain. The sleeve itself does not make a fit to the shaft, but a receptacle in the base of the sleeve contains a roller bearing. The outer race of this roller bearing makes a light driving fit to the sleeve. The inner race is fitted to the shaft by heating the race to a temperature 240 deg. fahr. in raw linseed oil, and then shrinking it on the shaft at the base. The cup of the upper roller bearing is contained in the wheel hub; the cone, which is a light drive fit to the shaft, is pushed into place by an adjusting nut. The eccentrics are placed below the wheel hub, making a close fit to the sleeve. Slip rings over the eccentrics impart a reciprocating motion to the rod lines. The eccentrics are placed at an angle of 180 deg. to each other.

To revert to the strains upon the roller bearings, there are two forces exerted, the radial load and the thrust load. Both the upper and the lower bearing share the radial load exerted by the force of the prime mover and the action of the wells and surface equipment. When the power is motionless, there is only the thrust load, caused by the actual weight of the power, exerted on the lower roller bearing. When the power is in motion, both bearings take the radial load, and the thrust load becomes negligible if the strain rods are rightly placed, and the wells are balanced.

Eccentric Rings

Eccentric rings must be built to withstand the radial force exerted by the pull of equipment, and it must be heavy enough to care for the intense strain of starting. One test made of an eccentric ring with an inside diameter of 39 in. showed an elongation through the diameter of 0.010 in., which amounts to 0.00023 in. elongation per inch. In this case a load of 20,160 lb. was suspended from one of the clevis-pin holes.

The wheel itself is subject only to the force brought upon it by the belt transmitting the horsepower. This force tends to collapse the wheel, and an 18-ft. bandwheel must sustain a load of 10,900 lb. under ordinary oil-country belting conditions.

Principal Forces Exerted

The principal forces exerted on the power are the force of the prime mover exerted through the wheel and hub to drive the power, and the force exerted by the wells and equipment which may be expressed as a drag upon the rings and eccentrics.

The force exerted by the prime mover is constant for a given speed, but its effective work is dependent upon its application to the bandwheel. Bandwheels are constructed in sizes suitable to requirements, and the ratio may be kept between the prime mover and the stroke of the wells such that pulley sizes will permit a belt of proper width and belt speed to be used. Oil-field belt is rated as delivering 1 hp. per 1 in. width at a belt speed of 350 ft. per min.

Horsepower Necessary

Horsepower necessary on a basis of delivery from the prime mover should give the engineer a starting point from which to figure his requirements. The fluid weight may be easily computed. The lift is also a known quantity, as is the number of strokes per minute. This, however, is not the ultimate horsepower necessary when all factors are taken into account.

An Axelson hydraulic tester showed a starting load of 19,200 lb. on a well 3080 ft. deep, having a 54-in. stroke 20 strokes per minute. For the 3-in. tubing used the known fluid load is about 2570 lb., requiring 21 hp. to lift it. The remaining 11,490 lb. is the dead lift of inertia.

It would require 31 hp. to overcome the inertia or 52 hp. simply

to start the well. The surface conditions raise the requirements to 100 hp. for the lease of 10 wells.

An Absorption Unit

The power is unquestionably an absorption unit for a complicated system of forces. Its function has been performed when it has negated these forces in relation to each other, has overcome the primary inertia, and has established regular reciprocating motion to the rod lines.

Such a function calls into play loads which bring tremendous pressures on the bearing surface of the ring, eccentric, and shaft of the power. Should there be no balance of forces there is a concentration of load on a limited area of bearing which is destined to cause undue friction, binding, and faulty lubrication which tends to the ultimate destruction of the power.

The actual mechanical forces, other than the prime mover, acting on the power might be illustrated by the simple self-propelled merry-go-round.

A blunt-nosed pole supports a cap, from which is suspended a ring. Improper balance will cause the ring to swing in against the pole. Imagine the ring to be eccentric, and also imagine a part similar to an eccentric inserted within the ring. Any force acting upon the ring must be transmitted to the eccentric. Any off-balance forces the ring against the eccentric.

Balance in Equipment

Now consider the ring of the merry-go-round apparatus balanced but motionless. It will require considerable force to set it in motion. This corresponds to the kick imparted to the power by the prime mover. Motion thus given to the merry-go-round is maintained by a slight motion of the bodies in balance, and at some point in the revolution of the wheel there is apparent slack. It is apparent that any outside unequalized force on the ring causes unbalance. The same forces illustrated are those brought to play in the power. A load on one side of one ring will not carry an initial starting load which has a great weight of fluid in addition to the deadweight of the surface and well equipment. Balance in equipment is very necessary because of the variation of fluid load. The fluid load is taken care of by the prime mover, which must care for this load even after the power is in motion.

Powers are designed with the idea of relief from the heavy strains at some point in their revolution. This is shown in the use of the two eccentrics, upper and lower, and in their position of 180 deg. to each other. Without this relief which exists in the form of balance, the problem of correct lubrication would be difficult. This relief is comparable to the slack in the merry-go-round arrangement.

The foregoing discussion speaks much of balance and unbalance, and somewhat of the prime mover. Many inquiries come to the manufacturer as to what horsepower is necessary for a bandwheel power job. A manufacturer can give the horsepower needed to lift a certain amount of fluid in a certain size of working barrel at a certain stroke and speed. Table 1 gives these data from which may be computed the power necessary for various depths under the given conditions. These take account of nothing but direct lift, and a clear knowledge of the other variables working against the power must be presented if a buyer is to receive the most economical and satisfactory equipment. These variable factors are the very factors determining the balance of the wheel. The factors which must be considered are the following ones:

Location of future wells
Will present equipment meet future demands?

Well Conditions

Depth of wells
Strength of sucker rods
Fluid conditions
Nature of fluid
Fluid weight equalized
Straightness of hole
Future fluid conditions.

Surface Conditions

On a lease where the land is nearly level ideal conditions are

met for power installation. A minimum of friction is encountered, and no added strain is met in devices for acute change of direction. In land cut by ravines and gullies a system of hold-ups, hold-downs, and swings is requisite to give proper direction and tension to the rod lines. These must be laid out to produce a minimum of strain upon the power.

Balanced wells a mile from the power are efficiently pumped where the suspension of the rod lines is properly managed. Where rod lines are very long, compensation must be made in the stroke of the well due to temperature changes and stretch of the rod lines.

In order that there shall be a minimum loss of stroke due to the change of direction of forces in the pumping jack, it should be so designed that the rod line will keep a constant tension on it, otherwise jerky motion, loss of stroke, and consequent unbalance result.

Any attempt to move the load with a long, fast stroke requires more power than slower and less stroke. Stretch of sucker rods due to fluid load is another necessary factor to be considered.

Well Conditions

There has been no limit set as to the depth of wells handled by the bandwheel power. However, deep wells must be carefully balanced. Attention must be given to tubing and working barrel sizes so that they balance opposing wells. Also the opposing wells should be as nearly equidistant from the power as possible unless some form of mechanical balance is introduced.

Power requirement in respect to fluid loads, in its nature and quantity, gives the engineer the key to his figuring. Consideration, however, should be made of the prospect of the fluid load increasing. It is often the case that the heaviest demands come on a power when it has already handled heavy loads for a long time and may be in need of replacement by heavier equipment, especially where there is great increase in the amount of water in the well.

Proper balance is nearest attained when the weight of equipment on the descending well is so distributed that it will actually assist in lifting the load of the opposed well.

To gain maximum efficiency and be furnished the most suitable equipment the engineer must carefully lay out his power location, and present all the factors upon which economical and efficient power installation and use depends.

These powers are nearly all driven by the single-cylinder horizontal-type gas engine. The tendency to the four-stroke-cycle engine has become much more evident with the depletion of the gas supply; and because of its higher thermal economy, ruggedness, and steady power output it is being generally accepted over the two-stroke-cycle engine. Requirements vary from 25 to 100 hp. and are continuing to increase as wheels are made larger and wells go deeper.

Conclusion

There has been outlined the application of the single-cylinder horizontal-type gas engine to oil recovery methods. It predominates in the field as the most economical prime mover, the most accessible, and the most foolproof in the hands of the general run of operators.

Conservatively estimating that about one-seventh of the oil available has been recovered and that further recovery depends on the application of mechanical methods, it is apparent that a tremendous field of activity awaits the engineer.

Discussion

Edgar J. Kates.[3] In view of the author's interesting classification of the proper fields of application for two-stroke-cycle and four-stroke-cycle gas engines, it would be desirable for him to add some information on the relative costs of these two types of engines.

H. C. Dickinson.[4] In view of the remarks relative to the possible efficiency of oil-field pumping equipment, the writer wishes to say a few words for the comparatively simple and crude system which has been developed in the oil fields and is current practice at the present time.

Consider for a moment what the problem involves. There are several stations, anywhere from five to twenty, scattered over an area sometimes more than two miles in diameter, at each of which stations a small amount of power is required to drive a reciprocating pump. The problem which presents itself is to distribute such power as is needed to these various stations, and this must usually be done from a single central power station. Individual units are out of the question, both on account of the cost and labor of maintenance.

The system of power transmission which has been developed to meet this need consists of a single tension rod or wire running directly from the power station to each of the individual pumps. This rod is suspended on swinging supports and is subject only to longitudinal motion. Each individual rod is kept in tension, and the several stations are balanced to a certain extent against each other. It should be borne in mind also that these transmission members must be mounted over all sorts of territory, sometimes in such a way as to interfere as little as possible with cultivation.

If one considers the fundamental mechanics of this problem and recalls the various possible mechanical devices which would be adapted for this purpose, it seems almost inconceivable that any of the devices commonly used or available could accomplish the pumping operation with anything approaching the overall efficiency or at a price comparable with that of the present system. The power loss in the transmission mechanisms themselves is confined almost entirely to the imperfect elasticity of the tension members. The efficiency of the pumps and of the central driving mechanism might possibly be improved. The pump, however, is an age-old contrivance, and it is doubtful whether it could be greatly improved for the existing conditions.

One might, for instance, conceive of a pneumatic or hydraulic system, or of a belt or rope drive or shaft. It requires only the briefest consideration to realize that any one of these mechanisms would be vastly more expensive in first cost and in cost of upkeep, as well as vastly lower in efficiency than the present system.

When one considers also the fact that the installation operation and general maintenance of these pumping equipments are usually in the hands of operators with the slightest possible mechanical experience and most meager facilities, the comparative merit of the present crude pumping system becomes even more obvious.

Joint Use of Diesel and Steam Engines to Balance Heat and Power

By EDGAR J. KATES,[1] NEW YORK, N. Y.

This paper deals with the use of Diesel engines in steam-power plants supplying both heat and power, the purpose being to increase the efficiency of steam utilization. This is accomplished by reducing the amount of unused exhaust steam and results in lower over-all costs for power and heat. The meaning of "exhaust-use factor" is illustrated by simplified examples. Similar examples are used to show the effect of Diesel power on over-all thermal economy and upon over-all costs.

TO BALANCE heat and power means, for the purpose of this paper, to utilize most economically space-heating and process steam in providing by-product power. It applies to industrial power plants supplying low-pressure steam or hot water as well as power. It also applies to power plants serving large city buildings such as office and loft buildings, department stores, clubs, and hotels. In such buildings the heat and power requirements imposed by human needs for illumination, elevator service, ventilation, and space-heating are quite similar in character to the demands of an industrial establishment, and both may be studied in the same way.

Importance of the Heat-Balance Problem

Engineers have long been aware that, by suitably selecting the steam-power equipment in such plants, the relative consumption of steam for power and heat may be so adjusted that the optimum quantity of steam will be used doubly. Such effective utilization of steam, with due regard to the investment charges, will cut to a minimum the over-all cost of heat and power.

There are many plants where this desirable balance has never been achieved. There are still others where the balance that once existed has been destroyed by the march of progress. In many industrial and commercial establishments the demand for power is increasing more rapidly than that for heat. The ratio is changing because the general trend of industrial progress is toward the more efficient use of steam in heating and process work, thus reducing the quantity of steam per unit of product, while at the same time the growing use of machinery is steadily increasing the power required per unit of product. Similarly, in large buildings, such as department stores, heat demands have changed but little, while power requirements have grown rapidly on account of the introduction of high-speed elevators, escalators, and air-conditioning systems, as well as increased illumination.

If, at all times of the day and at all seasons of the year, the consumption of heating steam is sufficient to develop as a by-product, in an ordinary steam plant, all of the power needed, the heat balance may be considered perfect from a practical standpoint.

But such conditions are not frequent. Generally the heating steam is deficient for part or all of the time, and the problem of reducing the cost of the prime power then becomes complex. Many methods are available—high steam pressure, extraction turbines, public-utility interconnections, etc. The attention which engineers have been giving this subject is evidenced by the many excellent analyses that have been published,[2] and also by numerous recent installations of high-pressure equipment and extraction turbines.

However, in endeavoring to reduce the cost of the prime steam power, engineers have generally limited themselves to modifications in the steam plant itself and have disregarded the possible use of Diesel engines for supplementing ordinary steam equipment and improving the over-all economy. The Diesel engine claims attention "when, as, and if" its fuel cost per kilowatt-hour is less than that of a steam-power plant whose exhaust heat is being wasted. Whether the addition of Diesel power is a better solution than a major alteration in the steam-power plant itself depends upon so many variable conflicting factors that it can be decided only after careful engineering analysis of each individual case. The purpose of this paper is merely to show that the Diesel alternative deserves careful consideration along with the others.

Fond as the engineer is of the B.t.u., it must be recognized at the outset of any study involving the joint use of Diesel and steam engines that a thermal analysis alone will not have any practical meaning. This for the reason that there is a great difference in the monetary value of a B.t.u. in the form of boiler oil and a B.t.u. in the form of Diesel fuel, the latter being 25 to 75 per cent more expensive. A study of this sort must therefore be primarily economic with heat values always converted into dollar values.

Scope of the Paper

It is the intention to confine this paper strictly to the subject of improving the economy of a steam-power plant by the use of Diesel engines. It is obvious that steam-plant economy can be improved also in many other ways, but these methods are not within the scope of the paper, and neither are the many methods of altering the relations between power and heat requirements at points of utilization. The fact is that even the subject of using Diesel engines in steam plants is too broad for complete treatment in this paper. Consequently, only one type of steam plant will be considered in detail—a moderate pressure

[1] Consulting Engineer. Mr. Kates was graduated from Columbia University with the degrees of B.A. and M.E., and then was employed in the Diesel-engine department of the De La Vergne Machine Company. For eight years he was Chief Engineer. Subsequently he has been in independent professional practice in Diesel-engine design and power-plant work. He was for three years Lecturer on Diesel engines at the Polytechnic Institute of Brooklyn and was for four terms Chairman of the Oil and Gas Power Division, A.S.M.E.

(150 lb. to 175 lb.) non-condensing plant with a seasonal variation in steam consumption for space-heating and process requirements. Such plants are sufficiently common to give the study practical value, and the principles derived from the one type of steam plant can readily be applied to others.

The purpose of the paper is to show the principles involved rather than to derive definite figures for specific cases. The principles cannot be demonstrated by working out in full detail various plant arrangements, as so many factors are included that the relative effect of each would be concealed in the final figures. Of course, that is the only way a specific case can be worked out in practice, but the number of different plant arrangements to be considered in a practical problem can be readily reduced by a clear grasp of the general principles. At a future time it is hoped to amplify the subject by records of the actual operating performance of joint Diesel and steam power plants.

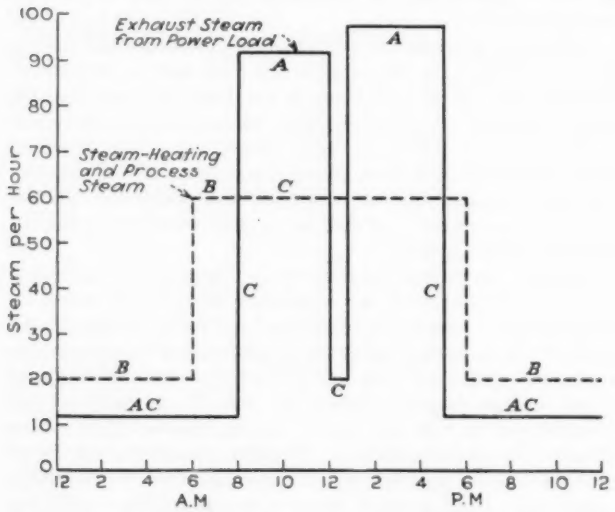

FIG. 1 STEAM LOAD CURVES, ILLUSTRATING USE OF FACTOR C/A

UTILIZATION OF EXHAUST STEAM

The economy of a joint Diesel and steam power plant is closely related to the ratios between the amount of steam doubly used for heat and power and the amounts used for either heat or power alone. These heat-use factors are illustrated by Fig. 1, which is an assumed chart of steam consumption for power and for heat (in an all-steam power plant) during a 24-hour period.

In this illustration A is the exhaust-steam output of the steam-power plant (which varies with the power load); B is the low-pressure steam consumed in space-heating and process, i.e., the "heat load;" and C is the engine exhaust-steam utilized (i.e., the portion of A that is also used to supply the heat load). Then:

- C/A = "exhaust-use factor" (shows proportion of steam power that is by-product)
- B/A = ratio of heat load to exhaust output
- C/B = proportion of heat load supplied by exhaust (remainder is heat to be supplied by reducing valve)
- B-C = heat supplied by reducing valve
- A-C = unused exhaust steam (corresponding to "prime" steam power).

Although it is the heat load B which makes possible the double use of steam for heat and power, the thermal analysis must start at the other end, i.e., the power load, inasmuch as an installed steam-power plant has a definite power capacity, and the real question is how much of the exhaust output of that power capacity can be utilized for heating. In other words, it is essential that the exhaust-use factor C/A should be large

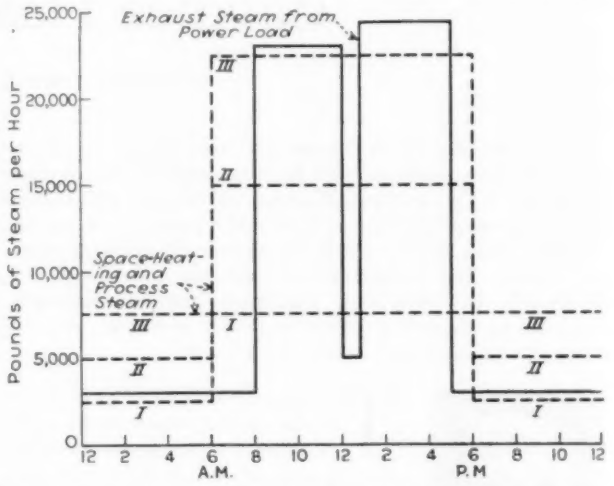

FIG. 2 COMPARISON OF POWER STEAM WITH VARYING REQUIREMENTS FOR HEATING STEAM

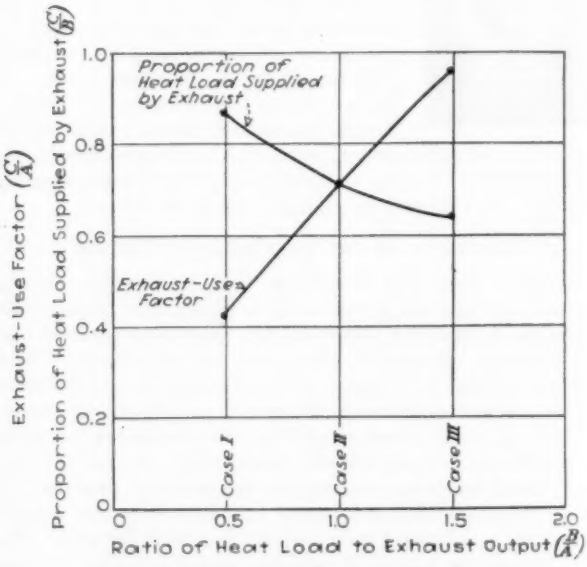

FIG. 3 RELATIONS OF HEAT-USE FACTORS

(to increase the proportion of by-product power), whereas it matters little what proportion of the heat load is supplied by the exhaust, i.e., C/B (since the remaining heat load must be supplied by the boilers in any case).

The exhaust-use factor is an extremely important consideration in studies of heat and power balance, and it must be correctly derived. Daily, monthly, or annual averages of heat and power consumption cannot be used directly in studies of private power plants unless the exhaust-use factors at all times are definitely known. This is made clear in Fig. 2, showing the assumed steam

TABLE 1 HEAT-USE FACTORS CORRESPONDING TO LOAD CURVES OF FIG. 2

	Symbol	Case I	Case II	Case III
Ratio of heat load to exhaust output...	B/A	0.50	1.00	1.50
Exhaust-use factor	C/A	0.43	0.71	0.95
Proportion of heat load supplied by exhaust	C/B	0.87	0.71	0.64
Unused exhaust, 1000 lb. per 24 hr.	A-C	136	70	10

consumption for power and heat over a 24-hour period in an all-steam power plant having the same power curve for each day of the year, but variable space-heating and process steam requirements as follows:

I Heating steam per day = 50 per cent of power-exhaust steam per day.

II Heating steam per day = 100 per cent of power-exhaust steam per day.

III Heating steam per day = 150 per cent of power-exhaust steam per day.

For the sake of clarity the graphs have been greatly simplified from practical conditions, but the general principles are not sacrificed. By "exhaust steam from power load" is understood the dry exhaust steam actually delivered to points of utilization—i.e., losses from drips and leakage having been deducted.

Table 1 and Fig. 3 show the heat-use factors computed from these graphs. It will be noted that the exhaust-use factor increases with the ratio of heat load to exhaust output; in other words, the percentage of by-product power increases as the heating load increases relative to the power load. But when the average heating load is equal to the power load (case II), the exhaust-use factor is only 71 per cent (instead of the ideal 100 per cent), and even when the average heating load is 50 per cent greater than the power load (case III), the engine exhaust is still not fully utilized. These simple relations have sometimes been overlooked, with the result that the amount of by-product power available has been overestimated.

Furthermore, it is evident that if the ratio of exhaust-steam utilization will be estimated too high if computed from *daily* averages, the error will be much worse if monthly, seasonal, or annual averages are used. Therefore when estimating future performance or analyzing past performance of actual plants, greatly detailed studies must be made. Such studies cannot be simplified by using averages for periods of a day or more, inasmuch as the amount of byproduct power produced is not dependent upon averages, but upon the simultaneous relations between the heat and power demands.[3]

In most cases it is necessary to obtain the characteristic heat- and power-load curves at different times of the year and also on different days of the week. Generally one must study the heat and power requirements for at least 50 days in the year.

A factory executive may remark that if power costs depend upon so many intricately related factors, any changes in manufacturing conditions that alter these factors will cause the power costs to deviate from the estimates. This is true, and is another reason why past predictions of costs have not always proved accurate. However, the cost variations will be much less in joint steam and Diesel plants than in all-steam plants, because the difference in cost between by-product power and prime power is much less in the combination plant.

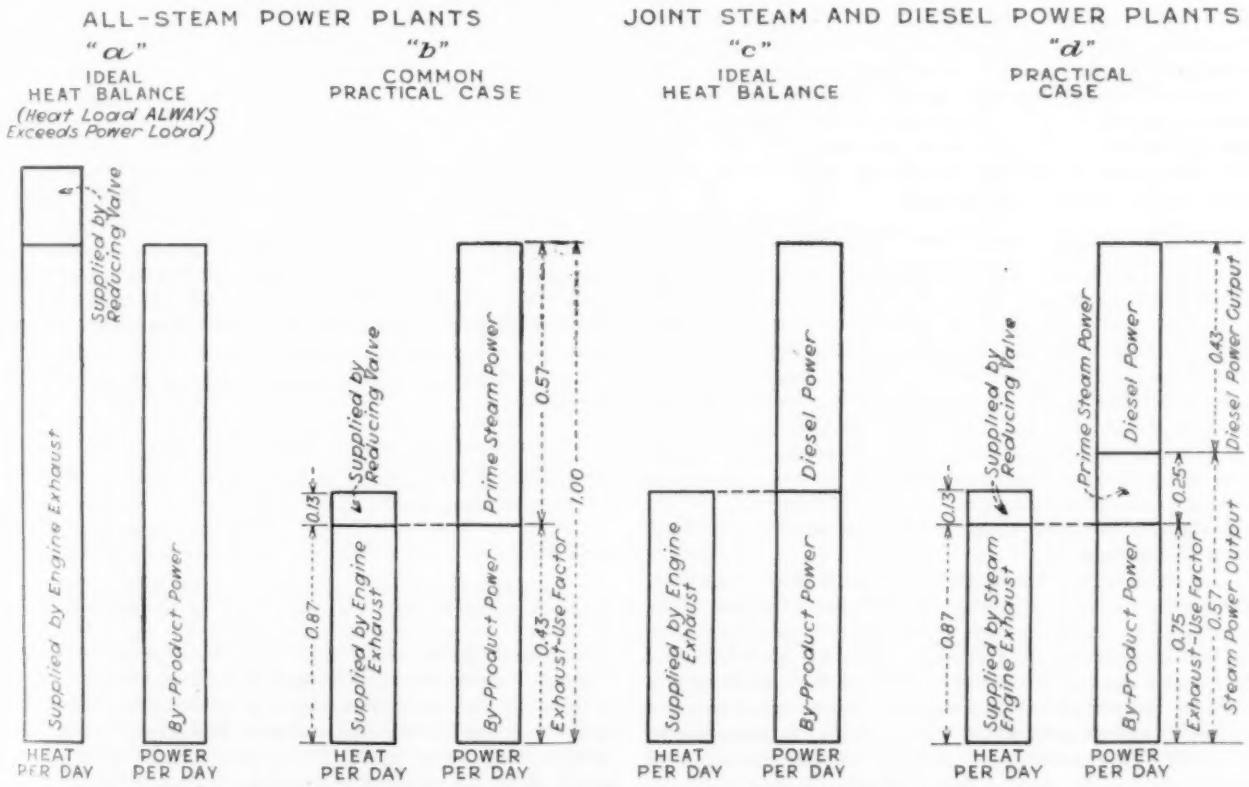

FIG. 4 THERMAL EFFECT OF ADDING DIESEL POWER TO A STEAM POWER PLANT

EFFECT OF DIESEL POWER ON OVER-ALL THERMAL ECONOMY

The addition of a Diesel engine to a steam-power plant may improve the over-all thermal economy in two ways: (a) by increasing the exhaust-use factor of the steam plant and (b) by replacing expensive "prime" steam power with less expensive Diesel power. This is illustrated by Fig. 4. Cases "*a*" and "*b*" refer to all-steam-power plants. Case "*a*" shows an ideal case based on the assumption that the heat load always exceeds the power load and that the exhaust steam is therefore fully

[3] The importance of coincidence in heat and power demands is diminished where heat-storage systems are employed, but even in such cases the heat demand can be controlled for only a comparatively short period.

utilized (exhaust-use factor 100 per cent). In this case all of the required power is produced as a by-product.

In "*b*" of Fig. 4 a common practical case is shown. The daily heat load is 50 per cent of the power load, i.e., B/A = 0.50 and the exhaust-use factor is 43 per cent. This results in 13 per cent of the heat load being supplied by reducing valves, while 57 per cent of the engine exhaust is wasted; i.e., 57 per cent of the power produced is "prime" steam power (and therefore costly).
